| sole                    |            |                     |       |       |                      |          |
| Only plan               | 1.12047    | .0568932            | 2.24  | 0.025 | 1.01433              | 1.237716 |
| _cons                   | 313.4879   | 134.6238            | 13.38 | 0.000 | 135.1083             | 727.3771 |

Note: `_cons` estimates baseline odds.

Among other things, we see that if the 401(k) is the only plan offered by the employer, then the odds of an employee participating increase by a factor of 1.12. We can also see that if the matching rate goes from 0 to 1:1 (exactly matching employee contributions) or from 1:1 to 2:1 (doubling employee contributions), then the odds of participating increase by 3.1.

The use of an odds-ratio interpretation is not appropriate if the conditional mean cannot be viewed as a probability. For example, if the fractional outcome were a Gini coefficient, we could not interpret the expected values of our outcomes as probabilities. The Gini coefficient is a measure of inequality between zero and one and cannot be interpreted as a probability. In this case, using the odds-ratio option would not be sensible.

## Stored results

fracreg stores the following in `e()`:

### Scalars

|                            |                                           |
|----------------------------|-------------------------------------------|
| <code>e(N)</code>          | number of observations                    |
| <code>e(k)</code>          | number of parameters                      |
| <code>e(k_eq)</code>       | number of equations in <code>e(b)</code>  |
| <code>e(k_eq_model)</code> | number of equations in overall model test |
| <code>e(k_dv)</code>       | number of dependent variables             |
| <code>e(df_m)</code>       | model degrees of freedom                  |

| <code>e(which)</code>        | max or min; whether optimizer is to perform maximization or minimization |
| <code>e(ml_method)</code>    | type of ml method                                                        |
| <code>e(user)</code>         | name of likelihood-evaluator program                                     |
| <code>e(technique)</code>    | maximization technique                                                   |
| <code>e(properties)</code>   | b V                                                                      |
| <code>e(estat_cmd)</code>    | program used to implement <code>estat</code>                             |
| <code>e(predict)</code>      | program used to implement <code>predict</code>                           |
| <code>e(marginsnotok)</code> | predictions disallowed by <code>margins</code>                           |
| <code>e(asbalanced)</code>   | factor variables <code>fvset</code> as <code>asbalanced</code>           |
| <code>e(asobserved)</code>   | factor variables <code>fvset</code> as <code>asobserved</code>           |

### Matrices

|                              |                                              |
|------------------------------|----------------------------------------------|
| <code>e(b)</code>            | coefficient vector                           |
| <code>e(mns)</code>          | vector of means of the independent variables |
| <code>e(Cns)</code>          | constraints matrix                           |
| <code>e(i_log)</code>        | iteration log (up to 20 iterations)          |
| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(V)</code>            | variance-covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

### Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

Matrices

`r(table)`

matrix containing the coefficients with their standard errors, test statistics, *p*-values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

The log-likelihood function for fractional models is of the form

$$\ln L = \sum_{j=1}^N w_j y_j \ln \{ G(\mathbf{x}'_j \boldsymbol{\beta}) \} + w_j (1 - y_j) \ln \{ 1 - G(\mathbf{x}'_j \boldsymbol{\beta}) \}$$

where  $N$  is the sample size,  $y_j$  is the dependent variable,  $w_j$  denotes the optional weights,  $\ln L$  is maximized, as described in [R] **Maximize**, and  $G(\cdot)$  can be

| Model     | Functional form for $G(\mathbf{x}'_j \boldsymbol{\beta})$                                 |
|-----------|-------------------------------------------------------------------------------------------|
| probit    | $\Phi(\mathbf{x}'_j \boldsymbol{\beta})$                                                  |
| logit     | $\exp(\mathbf{x}'_j \boldsymbol{\beta}) / \{1 + \exp(\mathbf{x}'_j \boldsymbol{\beta})\}$ |
| hetprobit | $\Phi \{ \mathbf{x}'_j \boldsymbol{\beta} / \exp(\mathbf{z}'_j \boldsymbol{\gamma}) \}$   |

where  $\mathbf{x}_j$  are the covariates for individual  $j$ ,  $\mathbf{z}_j$  are the covariates used to model the variance of the outcome for the heteroskedastic probit model, and  $\Phi$  is the standard normal cumulative density function.

## Postestimation commands

The following standard postestimation commands are available after `fracreg`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | conditional means, linear predictions, etc.                                                                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`forecast` and `hausman` are not appropriate with `svy` estimation results. `forecast` is also not appropriate with `mi` estimation results.

## predict

### Description for predict

`predict` creates a new variable containing predictions such as conditional means, linear predictions, standard errors, and equation-level scores.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i> | Description                                                    |
|------------------|----------------------------------------------------------------|
| cm               | conditional mean; the default                                  |
| xb               | linear prediction                                              |
| sigma            | standard deviation of the error term (for <code>het()</code> ) |
| stdp             | standard error of the linear prediction                        |

### Options for predict

#### Main

`cm`, the default, calculates the conditional mean of the outcome.

`xb` calculates the linear prediction.

`sigma` calculates the standard deviation of the error term. It is available only when `het()` is specified.

`stdp` calculates the standard error of the linear prediction.

`nooffset` is relevant only if you specified `offset(varname)`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j\mathbf{b}$  rather than as  $\mathbf{x}_j\mathbf{b} + \text{offset}_j$ .

`scores` calculates the equation-level scores. In the case of `fracreg probit` and `fracreg logit`,  $\partial \ln L / \partial (\mathbf{x}_j\boldsymbol{\beta})$  is calculated, and if the option `het()` was specified with `fracreg probit`, then  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$  is also calculated.

## margins

### Description for margins

`margins` estimates margins of response for conditional means and linear predictions.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>    | Description                                                    |
|---------------------|----------------------------------------------------------------|
| <code>cm</code>     | conditional mean; the default                                  |
| <code>xb</code>     | linear prediction                                              |
| <code>sigma</code>  | standard deviation of the error term (for <code>het()</code> ) |
| <code>stdp</code>   | not allowed with <code>margins</code>                          |
| <code>scores</code> | not allowed with <code>margins</code>                          |

Statistics not allowed with `margins` are functions of stochastic quantities other than `e(b)`.

For the full syntax, see [R] [margins](#).

## Remarks and examples

Remarks are presented under the following headings:

*Obtaining predicted values*  
*Performing hypothesis tests*

### Obtaining predicted values

Once you have fit a model using `fracreg`, you can obtain the conditional mean of the fractional response by using the `predict` command for both the estimation sample and other samples; see [U] [20 Estimation and postestimation commands](#) and [R] [predict](#).

When you use the fractional probit estimator, `fracreg probit`, with the option `het()`, there is an additional statistic available, `sigma`. With the `sigma` option, `predict` calculates the predicted standard deviation,  $\sigma_j = \exp(\mathbf{z}_j\boldsymbol{\gamma})$ .

## Performing hypothesis tests

### ▷ Example 1: Conditional means

In [example 1](#) of [\[R\] fracreg](#), we fit a fractional probit model to see how participation rate (`prate`) in 401(k) plans is affected by the matching rate of employer contributions (`mrate`). To obtain the predicted conditional means, we use `predict` and do not specify the default `cm` option.

| _cons                   | 3.25991     | .2323929            | 14.03 | 0.000 | 2.804429             | 3.715392  |

```
. predict mpart
(option cm assumed)
```

We can then summarize these conditional mean estimates (`cmean`) over the population to get the population average conditional mean participation rate in our sample.

```
. summarize mpart
```

| Variable | Obs   | Mean     | Std. dev. | Min      | Max      |
|----------|-------|----------|-----------|----------|----------|
| mpart    | 4,075 | .8405767 | .0828094  | .6251739 | .9964518 |

The average of the conditional mean of participation rate in our sample is 84% with a range between 62.5% and 99.6%.

► Example 2: Average marginal effects

In [example 2](#) of [R] `fracreg`, we used the outcome variable and covariates of [example 1](#) but instead of fitting a fractional probit regression, we fit a fractional logit. Using margins, we explore the average marginal effect of `mrater` on `prater` for both specifications.

Below, we use margins after `fracreg logit` with the option `post` to post the average marginal effects as estimates. We then store our results with the name `logit`. We do the same with our probit estimates.

```
. use https://www.stata-press.com/data/r19/401k, clear

|--------|----------|---------------------------|-------|-------|----------------------|----------|
| mrater | .1450106 | .0094558                  | 15.34 | 0.000 | .1264776             | .1635436 |

```
. estimates store logit
```

The marginal effects from `fracreg logit` suggest that a small change in the matching rate of employers can increase participation by more than 14%.

```
. quietly fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
. margins, dydx(mrate) post
Average marginal effects Number of obs = 4,075
Model VCE: Robust
Expression: Conditional mean of prate, predict()
dy/dx wrt: mrate
```

|       | Delta-method |           |       |       | [95% conf. interval] |          |
|-------|--------------|-----------|-------|-------|----------------------|----------|
|       | dy/dx        | std. err. | z     | P> z  |                      |          |
| mrate | .1335505     | .0087385  | 15.28 | 0.000 | .1164233             | .1506776 |

```
. estimates store probit
```

For the probit model, a change in the matching rate increases participation by more than 13%.

Because we stored our margins results as estimates, we can now produce a table showing both the logit and probit results.

```
. estimates table logit probit, se
```

| Variable | logit                  | probit                 |
|----------|------------------------|------------------------|
| mrate    | .14501059<br>.00945578 | .13355046<br>.00873852 |

Legend: b/se

As indicated by the standard errors in the table, both average marginal effects are significant. The difference between the two estimates is approximately one percentage point. This relatively small difference is consistent with the intuition that marginal effects obtained from probit and logit conditional means give us analogous results.

▷ Example 3: Average marginal effects for different levels of participation

We can also use margins to find the expected participation rate for various levels of employer matching. Using our probit model, we obtain the following by typing

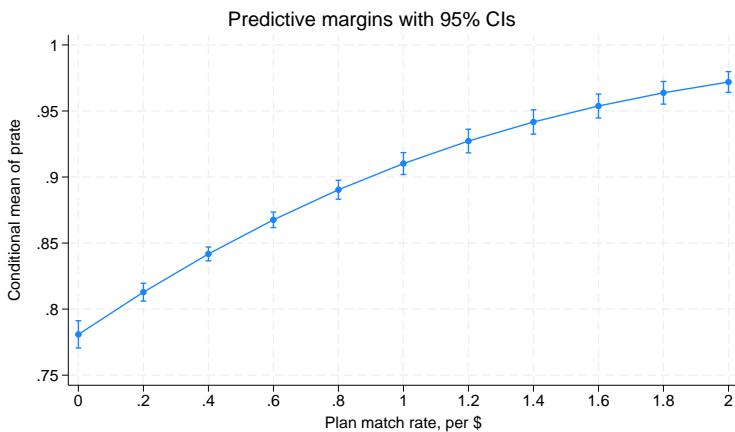

```
. quietly fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
. margins, at(mrate=(0(.2)2))
Predictive margins Number of obs = 4,075

2._at: mrate = .2
3._at: mrate = .4
4._at: mrate = .6
5._at: mrate = .8
6._at: mrate = 1
7._at: mrate = 1.2
8._at: mrate = 1.4
9._at: mrate = 1.6
10._at: mrate = 1.8
11._at: mrate = 2
```

|     | Delta-method |           |        |       |                      |
|-----|--------------|-----------|--------|-------|----------------------|
|     | Margin       | std. err. | z      | P> z  | [95% conf. interval] |
| _at |              |           |        |       |                      |
| 1   | .780858      | .0052738  | 148.06 | 0.000 | .7705216 .7911944    |
| 2   | .8128364     | .003441   | 236.22 | 0.000 | .8060923 .8195806    |
| 3   | .8417642     | .002672   | 315.03 | 0.000 | .8365271 .8470013    |
| 4   | .8675979     | .0029882  | 290.34 | 0.000 | .8617412 .8734547    |
| 5   | .8903734     | .0036591  | 243.33 | 0.000 | .8832018 .8975451    |
| 6   | .9101957     | .0042293  | 215.21 | 0.000 | .9019065 .9184849    |
| 7   | .9272265     | .0045767  | 202.60 | 0.000 | .9182563 .9361966    |
| 8   | .9416712     | .004694   | 200.61 | 0.000 | .9324711 .9508712    |
| 9   | .9537652     | .0046115  | 206.82 | 0.000 | .9447268 .9628035    |
| 10  | .9637608     | .004372   | 220.44 | 0.000 | .9551919 .9723298    |
| 11  | .9719159     | .0040207  | 241.73 | 0.000 | .9640355 .9797964    |

Going from no matching to equal matching changes the participation rate from 78% to 91%, and double matching moves participation all the way to 97.2%.

We can also see these results in a graph by using `marginplot`.

```
. marginplot
```

[Description](#)[Remarks and examples](#)[Quick start](#)[Stored results](#)[Menu](#)[Methods and formulas](#)[Syntax](#)[References](#)[Options](#)[Also see](#)

## Description

`frontier` fits stochastic production or cost frontier models; the default is a production frontier model. It provides estimators for the parameters of a linear model with a disturbance that is assumed to be a mixture of two components, which have a strictly nonnegative and symmetric distribution, respectively. `frontier` can fit models in which the nonnegative distribution component (a measurement of inefficiency) is assumed to be from a half-normal, exponential, or truncated-normal distribution. See [Kumbhakar and Lovell \(2000\)](#) for a detailed introduction to frontier analysis.

## Quick start

Cobb–Douglas production frontier model of `lny1` as a function of `lnx1` and `lnx2`

```
frontier lny1 lnx1 lnx2
```

Same as above, but use exponential instead of half-normal distribution for the inefficiency term

```
frontier lny1 lnx1 lnx2, distribution(exponential)
```

Include `x3` as an explanatory variable in the idiosyncratic error variance function

```
frontier lny1 lnx1 lnx2, vhet(x3)
```

Same as above, and include `x4` as an explanatory variable in the technical inefficiency variance function

```
frontier lny1 lnx1 lnx2, vhet(x3) uheth(x4)
```

Conditional mean model with the mean modeled as a linear function of `x3`

```
frontier lny1 lnx1 lnx2, distribution(tnormal) cm(x3)
```

Cost frontier model of `y2` as a function of `lnx1` and `lnx2`

```
frontier y2 lnx1 lnx2, distribution(tnormal) cost
```

\*`vce(robust)` and `vce(cluster clustvar)` may not be specified with `distribution(tnormal)`.

*indepvars* and *varlist* may contain factor variables; see [U] 11.4.3 Factor variables.

`bayesboot`, `bootstrap`, `by`, `collect`, `fp`, `jackknife`, `rolling`, and `statsby` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 `weight`.

`collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`noconstant`; see [R] [Estimation options](#).

`distribution(distname)` specifies the distribution for the inefficiency term as half-normal (`hnormal`), exponential, or truncated-normal (`tnormal`). The default is `hnormal`.

`ufrom(matrix)` specifies a  $1 \times K$  matrix of untransformed starting values when the distribution is truncated-normal (`tnormal`). `frontier` can estimate the parameters of the model by maximizing either the log likelihood or a transformed log likelihood (see [Methods and formulas](#)). `frontier` automatically transforms the starting values before passing them on to the transformed log likelihood. The matrix must have the same number of columns as there are parameters to estimate.

`cm(varlist [, noconstant])` may be used only with `distribution(tnormal)`. Here `frontier` will fit a conditional mean model in which the mean of the truncated-normal distribution is modeled as a linear function of the set of covariates specified in *varlist*. Specifying `noconstant` suppresses the constant in the mean function.

### Model 2

`constraints(constraints)`; see [R] [Estimation options](#).

By default, when fitting the truncated-normal model or the conditional mean model, `frontier` maximizes a transformed log likelihood. When constraints are applied, `frontier` will maximize the untransformed log likelihood with constraints defined in the untransformed metric.

`uhet(varlist [, noconstant])` specifies that the technical inefficiency component is heteroskedastic, with the variance function depending on a linear combination of *varlist*<sub>u</sub>. Specifying `noconstant` suppresses the constant term from the variance function. This option may not be specified with `distribution(tnormal)`.

`vhet(varlist [, noconstant])` specifies that the idiosyncratic error component is heteroskedastic, with the variance function depending on a linear combination of *varlist*<sub>v</sub>. Specifying `noconstant` suppresses the constant term from the variance function. This option may not be specified with `distribution(tnormal)`.

`cost` specifies that `frontier` fit a cost frontier model.

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

`vce(robust)` and `vce(cluster clustvar)` may not be specified with `distribution(tnormal)`.

### Reporting

`level(#)`, `nocnsreport`; see [R] [Estimation options](#).

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

## Maximization

`maximize_options`: `difficult`, `technique` (`algorithm_spec`), `iterate`(#), `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance`(#), `ltolerance`(#), `nrtolerance`(#), `nonrtolerance`, and `from` (`init_specs`); see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique` (`bhhh`) resets the default `vcetype` to `vce(opg)`.

The following options are available with `frontier` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Stochastic production frontier models were introduced by [Aigner, Lovell, and Schmidt \(1977\)](#) and [Meeusen and van den Broeck \(1977\)](#). Since then, stochastic frontier models have become a popular subfield in econometrics. [Kumbhakar and Lovell \(2000\)](#) provide a good introduction.

`frontier` fits three stochastic frontier models with distinct parameterizations of the inefficiency term and can fit stochastic production or cost frontier models.

Let's review the nature of the stochastic frontier problem. Suppose that a producer has a production function  $f(\mathbf{z}_i, \boldsymbol{\beta})$ . In a world without error or inefficiency, the  $i$ th firm would produce

$$q_i = f(\mathbf{z}_i, \boldsymbol{\beta})$$

Stochastic frontier analysis assumes that each firm potentially produces less than it might due to a degree of inefficiency. Specifically,

$$q_i = f(\mathbf{z}_i, \boldsymbol{\beta})\xi_i$$

where  $\xi_i$  is the level of efficiency for firm  $i$ ;  $\xi_i$  must be in the interval  $(0, 1]$ . If  $\xi_i = 1$ , the firm is achieving the optimal output with the technology embodied in the production function  $f(\mathbf{z}_i, \boldsymbol{\beta})$ . When  $\xi_i < 1$ , the firm is not making the most of the inputs  $\mathbf{z}_i$  given the technology embodied in the production function  $f(\mathbf{z}_i, \boldsymbol{\beta})$ . Because the output is assumed to be strictly positive (that is,  $q_i > 0$ ), the degree of technical efficiency is assumed to be strictly positive (that is,  $\xi_i > 0$ ).

Output is also assumed to be subject to random shocks, implying that

$$q_i = f(\mathbf{z}_i, \boldsymbol{\beta})\xi_i \exp(v_i)$$

Taking the natural log of both sides yields

$$\ln(q_i) = \ln\{f(\mathbf{z}_i, \boldsymbol{\beta})\} + \ln(\xi_i) + v_i$$

Assuming that there are  $k$  inputs and that the production function is linear in logs, defining  $u_i = -\ln(\xi_i)$  yields

$$\ln(q_i) = \beta_0 + \sum_{j=1}^k \beta_j \ln(z_{ji}) + v_i - u_i$$

Because  $u_i$  is subtracted from  $\ln(q_i)$ , restricting  $u_i \geq 0$  implies that  $0 < \xi_i \leq 1$ , as specified above.

Kumbhakar and Lovell (2000) provide a detailed version of the above derivation, and they show that performing an analogous derivation in the dual cost function problem allows us to specify the problem as

$$\ln(c_i) = \beta_0 + \beta_q \ln(q_i) + \sum_{j=1}^k \beta_j \ln(p_{ji}) + v_i + u_i$$

where  $q_i$  is output,  $z_{ji}$  are input quantities,  $c_i$  is cost, and the  $p_{ji}$  are input prices.

Intuitively, the inefficiency effect is required to lower output or raise expenditure, depending on the specification.

□ Technical note

The model that `frontier` actually fits is of the form

$$y_i = \beta_0 + \sum_{j=1}^k \beta_j x_{ji} + v_i - s u_i$$

where

$$s = \begin{cases} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{cases}$$

so, in the context of the discussion above,  $y_i = \ln(q_i)$ , and  $x_{ji} = \ln(z_{ji})$  for a production function; and for a cost function,  $y_i = \ln(c_i)$ , and the  $x_{ji}$  are the  $\ln(p_{ji})$  and  $\ln(q_i)$ . You must take the natural logarithm of the data before fitting a stochastic frontier production or cost model. `frontier` performs no transformations on the data.

□

Different specifications of the  $u_i$  and the  $v_i$  terms give rise to distinct models. `frontier` provides estimators for the parameters of three basic models in which the idiosyncratic component,  $v_i$ , is assumed to be independently  $N(0, \sigma_v)$  distributed over the observations. The basic models differ in their specification of the inefficiency term,  $u_i$ , as follows:

`exponential`: the  $u_i$  are independently exponentially distributed with variance  $\sigma_u^2$

`hnormal`: the  $u_i$  are independently half-normally  $N^+(0, \sigma_u^2)$  distributed

`tnormal`: the  $u_i$  are independently  $N^+(\mu, \sigma_u^2)$  distributed with truncation point at 0

For half-normal or exponential distributions, `frontier` can fit models with heteroskedastic error components, conditional on a set of covariates. For a truncated-normal distribution, `frontier` can also fit a conditional mean model in which the mean is modeled as a linear function of a set of covariates.

## ▶ Example 1: The half-normal and the exponential models

For our first example, we demonstrate the half-normal and exponential models by reproducing a study found in [Greene \(2003, 505\)](#), which uses data originally published in [Zellner and Revankar \(1969\)](#). In this study of the transportation equipment manufacturing industry, observations on value added, capital, and labor are used to estimate a Cobb–Douglas production function. The variable `lnv` is the log-transformed value added, `lnk` is the log-transformed capital, and `lnl` is the log-transformed labor. OLS estimates are compared with those from stochastic frontier models using both the half-normal and exponential distribution for the inefficiency term.

The parameter estimates and the estimates of the inefficiency terms closely match those published in [Greene \(2003, 505\)](#), but the standard errors of the parameter estimates are estimated differently (see the technical note below).

The output from `frontier` includes estimates of the standard deviations of the two error components,  $\sigma_v$  and  $\sigma_u$ , which are labeled `sigma_v` and `sigma_u`, respectively. In the log likelihood, they are parameterized as  $\ln\sigma_v^2$  and  $\ln\sigma_u^2$ , and these estimates are labeled `/lnsig2v` and `/lnsig2u` in the output. `frontier` also reports two other useful parameterizations. The estimate of the total error variance,  $\sigma_S^2 = \sigma_v^2 + \sigma_u^2$ , is labeled `sigma2`, and the estimate of the ratio of the standard deviation of the inefficiency component to the standard deviation of the idiosyncratic component,  $\lambda = \sigma_u/\sigma_v$ , is labeled `lambda`.

At the bottom of the output, `frontier` reports the results of a test that there is no technical inefficiency component in the model. This is a test of the null hypothesis  $H_0 : \sigma_u^2 = 0$  against the alternative hypotheses  $H_1 : \sigma_u^2 > 0$ . If the null hypothesis is true, the stochastic frontier model reduces to an OLS model with normal errors. However, because the test lies on the boundary of the parameter space of  $\sigma_u^2$ , the standard likelihood-ratio test is not valid, and a one-sided generalized likelihood-ratio test must be constructed; see [Gutierrez, Carter, and Drukker \(2001\)](#). For this example, the output shows LR = 0.43 with a  $p$ -value of 0.256 for the half-normal model and LR = 1.21 with a  $p$ -value of 0.135 for the exponential model. There are several possible reasons for the failure to reject the null hypothesis, but the fact that the test is based on an asymptotic distribution and the sample size was 25 is certainly a leading candidate among those possibilities.

◀

## □ Technical note

`frontier` maximizes the log-likelihood function of a stochastic frontier model by using the Newton–Raphson method, and the estimated variance–covariance matrix is calculated as the inverse of the negative Hessian (matrix of second partial derivatives); see [\[R\] ml](#). When comparing the results with those published using other software, be aware of the difference in the optimization methods, which may result in different, yet asymptotically equivalent, variance estimates.

□

## ▷ Example 2: Models with heteroskedasticity

Often the error terms may not have constant variance. `frontier` allows you to model heteroskedasticity in either error term as a linear function of a set of covariates. The variance of either the technical inefficiency or the idiosyncratic component may be modeled as

$$\sigma_i^2 = \exp(\mathbf{w}_i\boldsymbol{\delta})$$

The default constant included in  $\mathbf{w}_i$  may be suppressed by appending a `noconstant` option to the list of covariates. Also, you can simultaneously specify covariates for both  $\sigma_{u_i}$  and  $\sigma_{v_i}$ .

In this example, we use a sample of 756 observations of fictional firms producing a manufactured good by using capital and labor. The firms are hypothesized to use a constant returns-to-scale technology, but the sizes of the firms differ. Believing that this size variation will introduce heteroskedasticity into the idiosyncratic error term, we estimate the parameters of a Cobb–Douglas production function. To do this, we use a conditional heteroskedastic half-normal model, with the size of the firm as an explanatory variable in the variance function for the idiosyncratic error. We also perform a test of the hypothesis that the firms use a constant returns-to-scale technology.

```

The output above indicates that the variance of the idiosyncratic error term is a function of firm size. Also, we failed to reject the hypothesis that the firms use a constant returns-to-scale technology.

## □ Technical note

In small samples, the conditional heteroskedastic estimators will lack precision for the variance parameters and may fail to converge altogether.

## ▷ Example 3: The truncated-normal model

Let's turn our attention to the truncated-normal model. Once again, we will use fictional data. For this example, we have 1,231 observations on the quantity of output, the total cost of production for each firm, the prices that each firm paid for labor and capital services, and a categorical variable measuring the quality of each firm's management. After taking the natural logarithm of the costs ( $\ln\text{cost}$ ), prices ( $\ln p_k$  and  $\ln p_l$ ), and output ( $\ln\text{out}$ ), we fit a stochastic cost frontier model and specify the distribution for the inefficiency term to be truncated normal.

```

HO: No inefficiency component: z = 5.595 Prob >= z = 0.0000

In addition to the coefficients, the output reports estimates for several parameters. `sigma_v2` is the estimate of  $\sigma_v^2$ . `sigma_u2` is the estimate of  $\sigma_u^2$ . `gamma` is the estimate of  $\gamma = \sigma_u^2 / \sigma_S^2$ . `sigma2` is the estimate of  $\sigma_S^2 = \sigma_v^2 + \sigma_u^2$ . Because  $\gamma$  must be between 0 and 1, the optimization is parameterized in terms of the logit of  $\gamma$ , and this estimate is reported as `lgtgamma`. Because  $\sigma_S^2$  must be positive, the optimization is parameterized in terms of  $\ln(\sigma_S^2)$ , whose estimate is reported as `lnsigma2`. Finally, `mu` is the estimate of  $\mu$ , the mean of the truncated-normal distribution.

In the output above, the generalized log-likelihood test for the presence of the inefficiency term has been replaced with a test based on the third moment of the OLS residuals. When  $\mu = 0$  and  $\sigma_u = 0$ , the truncated-normal model reduces to a linear regression model with normally distributed errors. However, the distribution of the test statistic under the null hypothesis is not well established, because it becomes impossible to evaluate the log likelihood as  $\sigma_u$  approaches zero, prohibiting the use of the likelihood-ratio test.

However, [Coelli \(1995\)](#) noted that the presence of an inefficiency term would negatively skew the residuals from an OLS regression. By identifying negative skewness in the residuals with the presence of an inefficiency term, Coelli derived a one-sided test for the presence of the inefficiency term. The results of this test are given at the bottom of the output. For this example, the null hypothesis of no inefficiency component is rejected.

In the example below, we fit a truncated model and detect a statistically significant inefficiency term in the model. We might question whether the inefficiency term is identically distributed over all firms or whether there might be heterogeneity across firms. `frontier` provides an extension to the truncated normal model by allowing the mean of the inefficiency term to be modeled as a linear function of a set of covariates. In our dataset, we have a categorical variable that measures the quality of a firm’s management. We refit the model, including the `cm()` option, specifying a set of binary indicator variables representing the different categories of the quality-measurement variable as covariates.

| <code>e(which)</code>      | max or min; whether optimizer is to perform maximization or minimization |
| <code>e(ml_method)</code>  | type of ml method                                                        |
| <code>e(user)</code>       | name of likelihood-evaluator program                                     |
| <code>e(technique)</code>  | maximization technique                                                   |
| <code>e(properties)</code> | <code>b V</code>                                                         |
| <code>e(predict)</code>    | program used to implement <code>predict</code>                           |
| <code>e(asbalanced)</code> | factor variables <code>fvset</code> as <code>asbalanced</code>           |
| <code>e(asobserved)</code> | factor variables <code>fvset</code> as <code>asobserved</code>           |

### Matrices

|                              |                                              |
|------------------------------|----------------------------------------------|
| <code>e(b)</code>            | coefficient vector                           |
| <code>e(Cns)</code>          | constraints matrix                           |
| <code>e(ilog)</code>         | iteration log (up to 20 iterations)          |
| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(V)</code>            | variance–covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

### Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

Matrices

`r(table)`

matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Consider an equation of the form

$$y_i = \mathbf{x}_i\boldsymbol{\beta} + v_i - s u_i$$

where  $y_i$  is the dependent variable,  $\mathbf{x}_i$  is a  $1 \times k$  vector of observations on the independent variables included as indent covariates,  $\boldsymbol{\beta}$  is a  $k \times 1$  vector of coefficients, and

$$s = \begin{cases} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{cases}$$

The log-likelihood functions are as follows.

Normal/half-normal model:

$$\ln L = \sum_{i=1}^N \left\{ \frac{1}{2} \ln \left( \frac{2}{\pi} \right) - \ln \sigma_S + \ln \Phi \left( -\frac{s\epsilon_i \lambda}{\sigma_S} \right) - \frac{\epsilon_i^2}{2\sigma_S^2} \right\}$$

Normal/exponential model:

$$\ln L = \sum_{i=1}^N \left\{ -\ln \sigma_u + \frac{\sigma_v^2}{2\sigma_u^2} + \ln \Phi \left( \frac{-s\epsilon_i - \frac{\sigma_v^2}{\sigma_u}}{\sigma_v} \right) + \frac{s\epsilon_i}{\sigma_u} \right\}$$

Normal/truncated-normal model:

$$\ln L = \sum_{i=1}^N \left\{ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{\mu}{\sigma_S \sqrt{\gamma}} \right) + \ln \Phi \left[ \frac{(1-\gamma)\mu - s\gamma\epsilon_i}{\{\sigma_S^2\gamma(1-\gamma)\}^{1/2}} \right] - \frac{1}{2} \left( \frac{\epsilon_i + s\mu}{\sigma_S} \right)^2 \right\}$$

where  $\sigma_S = (\sigma_u^2 + \sigma_v^2)^{1/2}$ ,  $\lambda = \sigma_u/\sigma_v$ ,  $\gamma = \sigma_u^2/\sigma_S^2$ ,  $\epsilon_i = y_i - \mathbf{x}_i\boldsymbol{\beta}$ , and  $\Phi(\cdot)$  is the cumulative distribution function of the standard normal distribution.

To obtain estimation for  $u_i$ , you can use either the mean or the mode of the conditional distribution  $f(u|\epsilon)$ .

$$E(u_i | \epsilon_i) = \mu_{*i} + \sigma_* \left\{ \frac{\phi(-\mu_{*i}/\sigma_*)}{\Phi(\mu_{*i}/\sigma_*)} \right\}$$

$$M(u_i | \epsilon_i) = \begin{cases} \mu_{*i} & \text{if } \mu_{*i} \geq 0 \\ 0 & \text{otherwise} \end{cases}$$

Then, the technical efficiency ( $s = 1$ ) or cost efficiency ( $s = -1$ ) will be estimated by

$$E_i = E \{ \exp(-su_i) | \epsilon_i \}$$

$$= \left\{ \frac{1 - \Phi(s\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right\} \exp \left( -s\mu_{*i} + \frac{1}{2}\sigma_*^2 \right)$$

where  $\mu_{*i}$  and  $\sigma_*$  are defined for the normal/half-normal model as

$$\mu_{*i} = -s\epsilon_i\sigma_u^2/\sigma_S^2$$

$$\sigma_* = \sigma_u\sigma_v/\sigma_S$$

for the normal/exponential model as

$$\mu_{*i} = -s\epsilon_i - \sigma_v^2/\sigma_u$$

$$\sigma_* = \sigma_v$$

and for the normal/truncated-normal model as

$$\mu_{*i} = \frac{-s\epsilon_i\sigma_u^2 + \mu\sigma_v^2}{\sigma_S^2}$$

$$\sigma_* = \sigma_u\sigma_v/\sigma_S$$

In the half-normal and exponential models, when heteroskedasticity is assumed, the standard deviations,  $\sigma_u$  or  $\sigma_v$ , will be replaced in the above equations by

$$\sigma_i^2 = \exp(\mathbf{w}_i\boldsymbol{\delta})$$

where  $\mathbf{w}$  is the vector of explanatory variables in the variance function.

In the conditional mean model, the mean parameter of the truncated normal distribution,  $\mu$ , is modeled as a linear combination of the set of covariates,  $\mathbf{w}$ .

$$\mu = \mathbf{w}_i\boldsymbol{\delta}$$

Therefore, the log-likelihood function can be rewritten as

$$\ln L = \sum_{i=1}^N \left[ -\frac{1}{2} \ln(2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{\mathbf{w}_i \boldsymbol{\delta}}{\sqrt{\sigma_S^2 \gamma}} \right) + \ln \Phi \left\{ \frac{(1-\gamma) \mathbf{w}_i \boldsymbol{\delta} - s\gamma \epsilon_i}{\sqrt{\sigma_S^2 \gamma (1-\gamma)}} \right\} - \frac{1}{2} \left( \frac{\epsilon_i + s\mathbf{w}_i \boldsymbol{\delta}}{\sigma_S} \right)^2 \right]$$

The  $z$  test reported in the output of the truncated-normal model is a third-moment test developed by Coelli (1995) as an extension of a test previously developed by Pagan and Hall (1983). Coelli shows that under the null of normally distributed errors, the statistic

$$z = \frac{m_3}{\left( \frac{6m_2^3}{N} \right)^{1/2}}$$

has a standard normal distribution, where  $m_3$  is the third moment from the OLS regression. Because the residuals are either negatively skewed (production function) or positively skewed (cost function), a one-sided  $p$ -value is used.

## Postestimation commands

The following postestimation commands are available after `frontier`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| <code>hausman</code>         | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| <code>lrtest</code>          | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | predictions and their SEs, technical efficiency, etc.                                                                                   |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

# predict

## Description for predict

`predict` creates a new variable containing predictions such as linear predictions, standard errors, and estimates of technical efficiency.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic]
```

```
predict [type] stub* [if] [in], scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                   |                                                                                                         |
|-------------------|---------------------------------------------------------------------------------------------------------|
| <code>xb</code>   | linear prediction; the default                                                                          |
| <code>stdp</code> | standard error of the prediction                                                                        |
| <code>u</code>    | estimates of minus the natural log of the technical efficiency via $E(u_i   \epsilon_i)$                |
| <code>m</code>    | estimates of minus the natural log of the technical efficiency via $M(u_i   \epsilon_i)$                |
| <code>te</code>   | estimates of the technical efficiency via $E\{\exp(-su_i)   \epsilon_i\}$                               |
|                   | $s = \begin{cases} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{cases}$ |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`u` produces estimates of minus the natural log of the technical efficiency via  $E(u_i | \epsilon_i)$ .

`m` produces estimates of minus the natural log of the technical efficiency via  $M(u_i | \epsilon_i)$ .

`te` produces estimates of the technical efficiency via  $E\{\exp(-su_i) | \epsilon_i\}$ .

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_i \boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial (\ln \text{sig}2v)$ .

The third new variable will contain  $\partial \ln L / \partial (\ln \text{sig}2u)$ .

`scores` may not be specified after estimation with option `distribution(tnormal)`.

# margins

## Description for margins

`margins` estimates margins of response for linear predictions.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [options]
```

| <i>statistic</i>  | Description                           |
|-------------------|---------------------------------------|
| <code>xb</code>   | linear prediction; the default        |
| <code>stdp</code> | not allowed with <code>margins</code> |
| <code>u</code>    | not allowed with <code>margins</code> |
| <code>m</code>    | not allowed with <code>margins</code> |
| <code>te</code>   | not allowed with <code>margins</code> |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## Remarks and examples

### ▷ Example 1

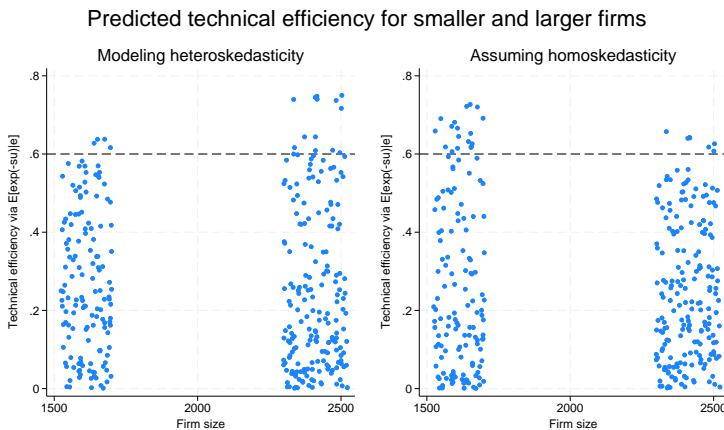

In [example 2](#) of [\[R\] frontier](#), we modeled heteroskedasticity by specifying the `vhet()` option. We would like to compare the predicted efficiency in that case with respect to a model specification without accounting for the presence of heteroskedasticity in the error term. [Kumbhakar and Lovell \(2000, 117\)](#) show that failing to account for heteroskedasticity associated with firm size may lead to bias in the estimation of the technical efficiency. By incorrectly assuming homoskedasticity, the estimates for relatively small firms would be biased upward, while the estimates for relatively large firms would be biased downward. Let's refit the model and use the `te` option of `predict`:

```
. use https://www.stata-press.com/data/r19/frontier1
. frontier lnoutput lnlabor lncapital, vhet(size)
 (output omitted)
. predict te_vhet, te
```

Next, we fit the model assuming homoskedasticity and then again predict the technical efficiency with the `te` option of `predict`:

```
. frontier lnoutput lnlabor lncapital
 (output omitted)
. predict te, te
```

The graph below shows the estimates for technical efficiency for the smaller and larger firms. The technical efficiency tends to be smaller for smaller firms when the model specification accounts for the presence of heteroskedasticity, whereas the predictions for the technical efficiency tends to be smaller for larger firms assuming homoskedasticity. These results agree with the theoretical statement in [Kumbhakar and Lovell \(2000\)](#) because the firm size was actually relevant to model heteroskedasticity in the idiosyncratic component of the error term.

## ▷ Example 2

We also test in [example 2](#) of [\[R\] frontier](#) whether the firms use constant returns to scale. We can use `lincom` as an alternative to perform an equivalent test based on the normal distribution.

```
. use https://www.stata-press.com/data/r19/frontier1, clear
. frontier lnoutput lnlabor lncapital, vhet(size)
 (output omitted)
. lincom _b[lnlabor] + _b[lncapital]-1
 (1) [lnoutput]lnlabor + [lnoutput]lncapital = 1
```

| lnoutput | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|----------|-------------|-----------|------|-------|----------------------|----------|
| (1)      | .1022278    | .5888511  | 0.17 | 0.862 | -1.051899            | 1.256355 |

The  $p$ -value is exactly the same as the one we obtained with the `test` command in [example 2](#) of [\[R\] frontier](#). However, notice that by using `lincom`, we obtained an estimate of the deviation from the constant returns-to-scale assumption, which is not significantly different from zero in this case.

## Description

`fvrevar` creates a variable list that includes equivalent, temporary variables in place of the factor variables, interactions, or time-series-operated variables in *varlist*. The resulting variable list can be used by commands that do not otherwise support factor variables or time-series-operated variables. The resulting list also could be used in a program to speed execution at the cost of using more memory.

## Quick start

Create temporary indicator variables for the levels of categorical variable `a` and store names in `r(varlist)`

```
fvrevar i.a
```

Create temporary variables corresponding to the levels of `a`, `b`, and their interaction

```
fvrevar i.a##i.b
```

Same as above, and create a temporary variable for the lag of `x` using `tsset` data

```
fvrevar i.a##i.b L.x
```

Return the list of unoperated variables (`a`, `b`, and `x`) in `r(varlist)`

```
fvrevar i.a##i.b L.x, list
```

Create new variables `a_1`, `a_2`, ..., corresponding to the levels of `a`

```
fvrevar i.a, stub(a_)
```

Create new variables `ab_1`, `ab_2`, ..., corresponding to the levels of the interaction between `a` and `b`

```
fvrevar i.a#i.b, stub(ab_)
```

## Syntax

```
fvrevar [varlist] [if] [in] [, substitute tsonly list stub(stub)]
```

You must `tsset` your data before using `fvrevar` if *varlist* contains time-series operators; see [TS] `tsset`. `collect` is allowed; see [U] 11.1.10 Prefix commands.

## Options

`substitute` specifies that equivalent, temporary variables be substituted for any factor variables, interactions, or time-series-operated variables in *varlist*. `substitute` is the default action taken by `fvrevar`; you do not need to specify the option.

`tsonly` specifies that equivalent, temporary variables be substituted for only the time-series-operated variables in *varlist*.

`list` specifies that all factor-variable operators and time-series operators be removed from *varlist* and the resulting list of base variables be returned in `r(varlist)`. No new variables are created with this option.

`stub(stub)` specifies that `fvrevar` generate named variables instead of temporary variables. The new variables will be named *stub#*.

## Remarks and examples

`fvrevar` might create no new variables, one new variable, or many new variables, depending on the number of factor variables, interactions, and time-series operators appearing in *varlist*. Any new variables created are temporary. The new, equivalent *varlist* is returned in `r(varlist)`. The new *varlist* corresponds one to one with the original *varlist*.

### ▷ Example 1

Typing

```
. use https://www.stata-press.com/data/r19/auto2
. fvrevar i.rep78 mpg turn
```

creates five temporary variables corresponding to the levels of `rep78`. No new variables are created for variables `mpg` and `turn` because they do not contain factor-variable or time-series operators.

The resulting variable list is

```
. display "r(varlist)"
__000000 __000001 __000002 __000003 __000004 mpg turn
```

(Your temporary variable names may be different, but that is of no consequence.)

Temporary variables automatically vanish when the program concludes.

## ▷ Example 2

Suppose we want to create temporary variables for specific levels of a factor variable. To do this, we can use the parenthesis notation of factor-variable syntax.

```
. fvrevar i(2,3)bn.rep78 mpg
```

creates two temporary variables corresponding to levels 2 and 3 of `rep78`. Notice that we specified that neither level 2 nor 3 be set as the base level by using the `bn` notation. If we did not specify `bn`, level 2 would have been treated as the base level.

The resulting variable list is

```
. display "r(varlist)"
__000005 __000002 mpg
```

We can see the results by listing the new variables alongside the original value of `rep78`.

```
. list rep78 'r(varlist)' in 1/5
```

|    | rep78   | __000005 | __000002 | mpg |
|----|---------|----------|----------|-----|
| 1. | Average | 0        | 1        | 22  |
| 2. | Average | 0        | 1        | 17  |
| 3. | .       | .        | .        | 22  |
| 4. | Average | 0        | 1        | 20  |
| 5. | Good    | 0        | 0        | 15  |

If we had needed only the base-variable names, we could have specified

```
. fvrevar i(2,3)bn.rep78 mpg, list
. display "r(varlist)"
mpg rep78
```

The order of the list will probably differ from that of the original list; base variables are listed only once.

## ▷ Example 3

Now let's assume we have `varlist` containing both an interaction and time-series-operated variables. If we want to create temporary variables for the entire equivalent `varlist`, we can specify `fvrevar` with no options.

```
. generate t = _n
. tsset t
 time variable: t, 1 to 74
 delta: 1 unit
. fvrevar c.turn#i(2,3).rep78 L.mpg
```

The resulting variable list is

```
. display "r(varlist)"
__000006 __000007 __000008
```

If we want to create temporary variables only for the time-series–operated variables, we can specify the `tsonly` option.

```
. fvrevar c.turn#i(2,3).rep78 L.mpg, tsonly
```

The resulting variable list is

```
. display "r(varlist)'"
2.rep78#c.turn 3.rep78#c.turn __000008
```

Notice that `fvrevar` returned the expanded factor-variable list with the `tsonly` option.

## □ Technical note

`fvrevar`, substitute avoids creating duplicate variables. Consider

```
. fvrevar i.rep78 turn mpg i.rep78
```

`i.rep78` appears twice in the `varlist`. `fvrevar` will create only one set of new variables for the five levels of `rep78` and will use these new variables once in the resulting `r(varlist)`. Moreover, `fvrevar` will do this even across multiple calls:

```
. fvrevar i.rep78 turn mpg
. fvrevar i.rep78
```

`i.rep78` appears in two separate calls. At the first call, `fvrevar` creates five temporary variables corresponding to the five levels of `rep78`. At the second call, `fvrevar` remembers what it has done and uses the same temporary variables for `i.rep78`.

## Stored results

`fvrevar` stores the following in `r()`:

```
Macros
 r(varlist) the modified variable list or list of base-variable names
```

## Description

`fvset base`, `fvset design`, and `fvset clear` manage factor-variable settings, which identify the base level and specify how to accumulate statistics over levels. `fvset base` declares the base level for each specified variable; the default for factor variables without a declared base level is the lowest value. `fvset design` specifies how the `margins` command is to accumulate over the levels of a factor variable. `fvset clear` removes factor-variable settings for each variable in *varlist*. `fvset clear _all` removes all factor-variable settings from all variables.

`fvset report` reports the current factor-variable settings for each variable in *varlist*. `fvset` without arguments is a synonym for `fvset report`.

## Quick start

Set the base category of categorical variable `a1` to 3

```
fvset base 3 a1
```

Set the base category of `a2`, `a3`, and `a4` to each variable's largest observed value

```
fvset base last a2 a3 a4
```

Set the base category of `a5` to the most frequent category

```
fvset base frequent a5
```

Set `a6` to have no base category

```
fvset base none a6
```

Restore the default base category (first) for `a5`

```
fvset base default a5
```

Specify that `margins` should treat `a2` as though it is balanced

```
fvset design asbalanced a2
```

Clear factor-variable settings for `a2` to `a4`

```
fvset clear a2-a4
```

List factor-variable settings for all factor variables

```
fvset report
```

## Syntax

Declare base settings

```
fvset base base_spec varlist
```

Declare design settings

```
fvset design design_spec varlist
```

Clear the current settings

```
fvset clear varlist
```

Report the current settings

```
fvset report [varlist] [, base(base_spec) design(design_spec)]
```

| <i>base_spec</i>             | Description                     |
|------------------------------|---------------------------------|
| <code>default</code>         | default base                    |
| <code><u>f</u>irst</code>    | lowest level value; the default |
| <code><u>l</u>ast</code>     | highest level value             |
| <code><u>f</u>requent</code> | most frequent level value       |
| <code><u>n</u>one</code>     | no base                         |
| <code>#</code>               | nonnegative integer value       |

| <i>design_spec</i>                    | Description                                                 |
|---------------------------------------|-------------------------------------------------------------|
| <code>default</code>                  | default design                                              |
| <code><u>a</u>s<u>b</u>alanced</code> | accumulate using $1/k$ , $k$ = number of levels             |
| <code><u>a</u>s<u>o</u>bserved</code> | accumulate using observed relative frequencies; the default |

`collect` is allowed; see [U] 11.1.10 Prefix commands.

## Options

`base(base_spec)` restricts `fvset report` to report only the factor-variable settings for variables with the specified *base\_spec*.

`design(design_spec)` restricts `fvset report` to report only the factor-variable settings for variables with the specified *design\_spec*.

## Remarks and examples

### ▷ Example 1

Using `auto2.dta`, we include factor variable `i.rep78` in a regression:

```
. use https://www.stata-press.com/data/r19/auto2
(1978 automobile data)
. regress mpg i.rep78, baselevels
```

| Source   | SS         | df | MS         | Number of obs | = | 69     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 549.415777 | 4  | 137.353944 | F(4, 64)      | = | 4.91   |
| Residual | 1790.78712 | 64 | 27.9810488 | Prob > F      | = | 0.0016 |
|          |            |    |            | R-squared     | = | 0.2348 |
|          |            |    |            | Adj R-squared | = | 0.1869 |
| Total    | 2340.2029  | 68 | 34.4147485 | Root MSE      | = | 5.2897 |

| mpg       | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|-----------|-------------|-----------|-------|-------|----------------------|----------|
| rep78     |             |           |       |       |                      |          |
| Poor      | 0           | (base)    |       |       |                      |          |
| Fair      | -1.875      | 4.181884  | -0.45 | 0.655 | -10.22927            | 6.479274 |
| Average   | -1.566667   | 3.863059  | -0.41 | 0.686 | -9.284014            | 6.150681 |
| Good      | .6666667    | 3.942718  | 0.17  | 0.866 | -7.209818            | 8.543152 |
| Excellent | 6.363636    | 4.066234  | 1.56  | 0.123 | -1.759599            | 14.48687 |
| _cons     | 21          | 3.740391  | 5.61  | 0.000 | 13.52771             | 28.47229 |

We specified the `baselevels` option so that the base level would be included in the output. By default, the first level is the base level. We can change the base level to 2:

```
. fvset base 2 rep78
. regress mpg i.rep78, baselevels
```

| Source   | SS         | df | MS         | Number of obs | = | 69     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 549.415777 | 4  | 137.353944 | F(4, 64)      | = | 4.91   |
| Residual | 1790.78712 | 64 | 27.9810488 | Prob > F      | = | 0.0016 |
|          |            |    |            | R-squared     | = | 0.2348 |
|          |            |    |            | Adj R-squared | = | 0.1869 |
| Total    | 2340.2029  | 68 | 34.4147485 | Root MSE      | = | 5.2897 |

| mpg       | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|-----------|-------------|-----------|-------|-------|----------------------|----------|
| rep78     |             |           |       |       |                      |          |
| Poor      | 1.875       | 4.181884  | 0.45  | 0.655 | -6.479274            | 10.22927 |
| Fair      | 0           | (base)    |       |       |                      |          |
| Average   | .3083333    | 2.104836  | 0.15  | 0.884 | -3.896559            | 4.513226 |

| Fair      | 19.125      | 1.870195  | 10.23 | 0.000 | 15.38886             | 22.86114 |
| Average   | 19.43333    | .9657648  | 20.12 | 0.000 | 17.504               | 21.36267 |
| Good      | 21.66667    | 1.246797  | 17.38 | 0.000 | 19.1759              | 24.15743 |
| Excellent | 27.36364    | 1.594908  | 17.16 | 0.000 | 24.17744             | 30.54983 |

### ▷ Example 2

By default, margins assumes that factor variables are to be treated as observed and accumulates a margin by using the observed relative frequencies of the factor levels or the sum of the weights if weights have been specified.

```
. regress mpg i.foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 378.153515 | 1  | 378.153515 | F(1, 72)      | = | 13.18  |
| Residual | 2065.30594 | 72 | 28.6848048 | Prob > F      | = | 0.0005 |
|          |            |    |            | R-squared     | = | 0.1548 |
|          |            |    |            | Adj R-squared | = | 0.1430 |
| Total    | 2443.45946 | 73 | 33.4720474 | Root MSE      | = | 5.3558 |

| mpg     | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|---------|-------------|-----------|-------|-------|----------------------|----------|
| foreign |             |           |       |       |                      |          |
| Foreign | 4.945804    | 1.362162  | 3.63  | 0.001 | 2.230384             | 7.661225 |
| _cons   | 19.82692    | .7427186  | 26.70 | 0.000 | 18.34634             | 21.30751 |

```
. margins
Predictive margins Number of obs = 74
Model VCE: OLS
Expression: Linear prediction, predict()
```

|       | Delta-method |           | t     | P> t  | [95% conf. interval] |          |
|-------|--------------|-----------|-------|-------|----------------------|----------|
|       | Margin       | std. err. |       |       |                      |          |
| _cons | 21.2973      | .6226014  | 34.21 | 0.000 | 20.05616             | 22.53843 |

Let's set foreign to always accumulate using equal relative frequencies:

```
. fvset design asbalanced foreign
. regress mpg i.foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|

At: foreign (asbalanced)
```

|       | Delta-method |           | t     | P> t  | [95% conf. interval] |          |
|-------|--------------|-----------|-------|-------|----------------------|----------|
|       | Margin       | std. err. |       |       |                      |          |
| _cons | 22.29983     | .6810811  | 32.74 | 0.000 | 20.94211             | 23.65754 |

Suppose that we issued the fvset design command earlier in our session and that we cannot remember which variables we set as asbalanced. We can retrieve this information by using the fvset report command:

```
. fvset report, design(asbalanced)
```

| Variable | Base | Design     |
|----------|------|------------|
| foreign  |      | asbalanced |

## □ Technical note

`margins` is aware of a factor variable's design setting only through the estimation results it is working with. The design setting is stored by the estimation command; thus changing the design setting between the estimation command and `margins` will have no effect. For example, the output from the following two calls to `margins` yields the same results:

```
. fvset clear foreign
. regress mpg i.foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|

□

## Stored results

`fvset` stores the following in `r()`:

Macros

```
r(varlist) varlist
r(baselist) base setting for each variable in varlist
r(designlist) design setting for each variable in varlist
```

[Description](#)[Options](#)[Acknowledgments](#)[Quick start](#)[Remarks and examples](#)[References](#)[Menu](#)[Stored results](#)[Also see](#)[Syntax](#)[Methods and formulas](#)

## Description

`glm` fits generalized linear models. It can fit models by using either IRLS (maximum quasilielihood) or Newton–Raphson (maximum likelihood) optimization, which is the default.

See [\[U\] 27 Overview of Stata estimation commands](#) for a description of all of Stata’s estimation commands, several of which fit models that can also be fit using `glm`.

## Quick start

Model of  $y$  as a function of  $x$  when  $y$  is a proportion

```
glm y x, family(binomial)
```

Logit model of  $y$  events occurring in 15 trials as a function of  $x$

```
glm y x, family(binomial 15) link(logit)
```

Probit model of  $y$  events as a function of  $x$  using grouped data with group sizes  $n$

```
glm y x, family(binomial n) link(probit)
```

Model of discrete  $y$  with user-defined family `myfamily` and link `mylink`

```
glm y x, family(myfamily) link(mylink)
```

Bootstrap standard errors in a model of  $y$  as a function of  $x$  with a gamma family and log link

```
glm y x, family(gamma) link(log) vce(bootstrap)
```

## Menu

Statistics > Generalized linear models > Generalized linear models (GLM)

## Syntax

```
glm depvar [indepvars] [if] [in] [weight] [, options]
```

| <i>options</i>                            | Description                                                                                                                                                                                                            |
|-------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

*indepvars* may contain factor variables; see [U] 11.4.3 Factor variables.

*depvar* and *indepvars* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fmm`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] `bayes: glm` and [FMM] `fmm: glm`.

`vce(bootstrap)`, `vce(jackknife)`, and `vce(jackknife1)` are not allowed with the `mi estimate` prefix; see [MI] `mi estimate`.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`aweight`s are not allowed with the `jackknife` prefix; see [R] `jackknife`.

`svy()`, `vfactor()`, `disp()`, `scale()`, `irls`, `fisher()`, `noheader`, `notable`, `nodisplay`, and `weights` are not allowed with the `svy` prefix; see [SVY] `svy`.

`fweights`, `aweight`s, `iweight`s, and `pweight`s are allowed; see [U] 11.1.6 `weight`.

`noheader`, `notable`, `nodisplay`, `collinear`, and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

Model

`family`(*familyname*) specifies the distribution of *depvar*; `family(gaussian)` is the default.

`link`(*linkname*) specifies the link function; the default is the canonical link for the `family()` specified (except for `family(nbinomial)`).

## Model 2

`noconstant`, `exposure(varname)`, `offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#). `constraints(constraints)` is not allowed with `irls`.

`asis` forces retention of perfect predictor variables and their associated, perfectly predicted observations and may produce instabilities in maximization; see [R] [probit](#). This option is allowed only with option `family(binomial)` with a denominator of 1.

`mu(varname)` specifies *varname* as the initial estimate for the mean of *depvar*. This option can be useful with models that experience convergence difficulties, such as `family(binomial)` models with power or odds-power links. `init(varname)` is a synonym.

## SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

In addition to the standard *vcetypes*, `glm` allows the following alternatives:

`vce(eim)` specifies that the EIM estimate of variance be used.

`vce(jackknife1)` specifies that the one-step jackknife estimate of variance be used.

`vce(hac kernel [#])` specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels built into `glm`. *kernel* is a user-written program or one of

`nwest` | `gallant` | `anderson`

`#` specifies the number of lags. If `#` is not specified,  $N - 2$  is assumed. If you wish to specify `vce(hac . . .)`, you must `tsset` your data before calling `glm`.

`vce(unbiased)` specifies that the unbiased sandwich estimate of variance be used.

`vfactor(#)` specifies a scalar by which to multiply the resulting variance matrix. This option allows you to match output with other packages, which may apply degrees of freedom or other small-sample corrections to estimates of variance.

`disp(#)` multiplies the variance of *depvar* by `#` and divides the deviance by `#`. The resulting distributions are members of the quasilielihood family. This option is allowed only with option `irls`.

`scale(x2 | dev | #)` overrides the default scale parameter. This option is allowed only with Hessian (information matrix) variance estimates.

By default, `scale(1)` is assumed for the discrete distributions (binomial, Poisson, and negative binomial), and `scale(x2)` is assumed for the continuous distributions (Gaussian, gamma, and inverse Gaussian).

`scale(x2)` specifies that the scale parameter be set to the Pearson  $\chi^2$  (or generalized  $\chi^2$ ) statistic divided by the residual degrees of freedom, which is recommended by [McCullagh and Nelder \(1989\)](#) as a good general choice for continuous distributions.

`scale(dev)` sets the scale parameter to the deviance divided by the residual degrees of freedom. This option provides an alternative to `scale(x2)` for continuous distributions and overdispersed or underdispersed discrete distributions. This option is allowed only with option `irls`.

`scale(#)` sets the scale parameter to `#`. For example, using `scale(1)` in `family(gamma)` models results in exponential-errors regression. Additional use of `link(log)` rather than the default `link(power -1)` for `family(gamma)` essentially reproduces Stata's `streg`, `dist(exp)` `nohr` command (see [ST] **streg**) if all the observations are uncensored.

---

#### Reporting

`level(#)`; see [R] **Estimation options**.

`eform` displays the exponentiated coefficients and corresponding standard errors and confidence intervals. For `family(binomial) link(logit)` (that is, logistic regression), exponentiation results are odds ratios; for `family(nbinomial) link(log)` (that is, negative binomial regression) and for `family(poisson) link(log)` (that is, Poisson regression), exponentiated coefficients are incidence-rate ratios.

`nocnsreport`; see [R] **Estimation options**.

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] **Estimation options**.

---

#### Maximization

`m1` requests that optimization be carried out using Stata's `m1` commands and is the default.

`irls` requests iterated, reweighted least-squares (IRLS) optimization of the deviance instead of Newton–Raphson optimization of the log likelihood. If the `irls` option is not specified, the optimization is carried out using Stata's `m1` commands, in which case all options of `m1 maximize` are also available.

*maximize\_options*: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] **Maximize**. These options are seldom used.

Setting the optimization method to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

If option `irls` is specified, only *maximize\_options* `iterate()`, `nolog`, `trace`, and `ltolerance()` are allowed. With `irls` specified, the convergence criterion is satisfied when the absolute change in deviance from one iteration to the next is less than or equal to `ltolerance()`, where `ltolerance(1e-6)` is the default.

`fisher(#)` specifies the number of Newton–Raphson steps that should use the Fisher scoring Hessian or EIM before switching to the observed information matrix (OIM). This option is useful only for Newton–Raphson optimization (and not when using `irls`).

`search` specifies that the command search for good starting values. This option is useful only for Newton–Raphson optimization (and not when using `irls`).

The following options are available with `glm` but are not shown in the dialog box:

`noheader` suppresses the header information from the output. The coefficient table is still displayed.

`notable` suppresses the table of coefficients from the output. The header information is still displayed.

`nodisplay` suppresses the output. The iteration log is still displayed.

`collinear`, `coeflegend`; see [\[R\] Estimation options](#). `collinear` is not allowed with `irls`.

## Remarks and examples

Remarks are presented under the following headings:

*General use*

*Variance estimators*

*User-defined functions*

### General use

`glm` fits generalized linear models of  $y$  with covariates  $\mathbf{x}$ :

$$g\{E(y)\} = \mathbf{x}\boldsymbol{\beta}, \quad y \sim F$$

$g(\cdot)$  is called the link function, and  $F$  is the distributional family. Substituting various definitions for  $g(\cdot)$  and  $F$  results in a surprising array of models. For instance, if  $y$  is distributed as Gaussian (normal) and  $g(\cdot)$  is the identity function, we have

$$E(y) = \mathbf{x}\boldsymbol{\beta}, \quad y \sim \text{Normal}$$

or linear regression. If  $g(\cdot)$  is the logit function and  $y$  is distributed as Bernoulli, we have

$$\text{logit}\{E(y)\} = \mathbf{x}\boldsymbol{\beta}, \quad y \sim \text{Bernoulli}$$

or logistic regression. If  $g(\cdot)$  is the natural log function and  $y$  is distributed as Poisson, we have

$$\ln\{E(y)\} = \mathbf{x}\boldsymbol{\beta}, \quad y \sim \text{Poisson}$$

or Poisson regression, also known as the log-linear model. Other combinations are possible.

Although `glm` can be used to perform linear regression (and, in fact, does so by default), this regression should be viewed as an instructional feature; `regress` produces such estimates more quickly, and many postestimation commands are available to explore the adequacy of the fit; see [\[R\] regress](#) and [\[R\] regress postestimation](#).

In any case, you specify the link function by using the `link()` option and specify the distributional family by using `family()`. The available link functions are

| Link function         | glm option                   |
|-----------------------|------------------------------|
| identity              | <code>link(identity)</code>  |
| log                   | <code>link(log)</code>       |
| logit                 | <code>link(logit)</code>     |
| probit                | <code>link(probit)</code>    |
| complementary log-log | <code>link(cloglog)</code>   |
| odds power            | <code>link(opower #)</code>  |
| power                 | <code>link(power #)</code>   |
| negative binomial     | <code>link(nbinomial)</code> |
| log-log               | <code>link(loglog)</code>    |
| log-complement        | <code>link(logc)</code>      |

Define  $\mu = E(y)$  and  $\eta = g(\mu)$ , meaning that  $g(\cdot)$  maps  $E(y)$  to  $\eta = \mathbf{x}\beta + \text{offset}$ .

Link functions are defined as follows:

`identity` is defined as  $\eta = g(\mu) = \mu$ .

`log` is defined as  $\eta = \ln(\mu)$ .

`logit` is defined as  $\eta = \ln\{\mu/(1 - \mu)\}$ , the natural log of the odds.

`probit` is defined as  $\eta = \Phi^{-1}(\mu)$ , where  $\Phi^{-1}(\cdot)$  is the inverse Gaussian cumulative.

`cloglog` is defined as  $\eta = \ln\{-\ln(1 - \mu)\}$ .

`opower` is defined as  $\eta = [\{\mu/(1 - \mu)\}^n - 1]/n$ , the power of the odds. The function is generalized so that `link(opower 0)` is equivalent to `link(logit)`, the natural log of the odds.

`power` is defined as  $\eta = \mu^n$ . Specifying `link(power 1)` is equivalent to specifying `link(identity)`. The power function is generalized so that  $\mu^0 \equiv \ln(\mu)$ . Thus, `link(power 0)` is equivalent to `link(log)`. Negative powers are, of course, allowed.

`nbinomial` is defined as  $\eta = \ln\{\mu/(\mu + k)\}$ , where  $k = 1$  if `family(nbinomial)` is specified,  $k = \#_k$  if `family(nbinomial #_k)` is specified, and  $k$  is estimated via maximum likelihood if `family(nbinomial ml)` is specified.

`loglog` is defined as  $\eta = -\ln\{-\ln(\mu)\}$ .

`logc` is defined as  $\eta = \ln(1 - \mu)$ .

The available distributional families are

| Family             | glm option                     |
|--------------------|--------------------------------|
| Gaussian (normal)  | <code>family(gaussian)</code>  |
| inverse Gaussian   | <code>family(igaussian)</code> |
| Bernoulli/binomial | <code>family(binomial)</code>  |
| Poisson            | <code>family(poisson)</code>   |
| negative binomial  | <code>family(nbinomial)</code> |
| gamma              | <code>family(gamma)</code>     |

`family(normal)` is a synonym for `family(gaussian)`.

The binomial distribution can be specified as 1) `family(binomial)`, 2) `family(binomial #N)`, or 3) `family(binomial varnameN)`. In case 2, #<sub>N</sub> is the value of the binomial denominator *N*, the number of trials. Specifying `family(binomial 1)` is the same as specifying `family(binomial)`. In case 3, *varname<sub>N</sub>* is the variable containing the binomial denominator, allowing the number of trials to vary across observations.

The negative binomial distribution can be specified as 1) `family(nbinomial)`, 2) `family(nbinomial #k)`, or 3) `family(nbinomial ml)`. Omitting #<sub>k</sub> is equivalent to specifying `family(nbinomial 1)`. In case 3, the value of #<sub>k</sub> is estimated via maximum likelihood. The value #<sub>k</sub> enters the variance and deviance functions. Typical values range between 0.01 and 2; see the [technical note](#) below.

You do not have to specify both `family()` and `link()`; the default `link()` is the canonical link for the specified `family()` (except for `nbinomial`):

| Family                         | Default link                |
|--------------------------------|-----------------------------|
| <code>family(gaussian)</code>  | <code>link(identity)</code> |
| <code>family(igaussian)</code> | <code>link(power -2)</code> |
| <code>family(binomial)</code>  | <code>link(logit)</code>    |
| <code>family(poisson)</code>   | <code>link(log)</code>      |
| <code>family(nbinomial)</code> | <code>link(log)</code>      |
| <code>family(gamma)</code>     | <code>link(power -1)</code> |

If you specify both `family()` and `link()`, not all combinations make sense. You may choose from the following combinations:

|                   | identity | log | logit | probit | cloglog | power | opower | nbinomial | loglog | logc |
|-------------------|----------|-----|-------|--------|---------|-------|--------|-----------|--------|------|
| Gaussian          | x        | x   |       |        |         | x     |        |           |        |      |
| inverse Gaussian  | x        | x   |       |        |         | x     |        |           |        |      |
| binomial          | x        | x   | x     | x      | x       | x     | x      |           | x      | x    |
| Poisson           | x        | x   |       |        |         | x     |        |           |        |      |
| negative binomial | x        | x   |       |        |         | x     |        | x         |        |      |
| gamma             | x        | x   |       |        |         | x     |        |           |        |      |

### □ Technical note

Some `family()` and `link()` combinations result in models already fit by Stata. These are

| family()  | link()   | Options                                                      | Equivalent Stata command                                    |

Notes:

1. The variance factor  $\#_v$  should be set to  $n/(n - k)$ , where  $n$  is the number of observations and  $k$  the number of regressors. If the number of regressors is not specified, the estimated standard errors will, as a result, differ by this factor.
2. Because the link is not the canonical link for the binomial family, you must specify the `vce(oim)` option if using `irls` to get equivalent standard errors. If `irls` is used without `vce(oim)`, the regression coefficients will be the same but the standard errors will be only asymptotically equivalent. If no options are specified (*nothing*), `glm` will optimize using Newton–Raphson, making it equivalent to the other Stata command.  
See [R] [cloglog](#) and [R] [probit](#) for more details about these commands.
3. Because the canonical link is being used, the standard errors will be equivalent whether the EIM or the OIM estimator of variance is used.
4. Family negative binomial, log-link models—also known as negative binomial regression models—are used for data with an overdispersed Poisson distribution. Although `glm` can be used to fit such models, using Stata’s maximum likelihood `nbreg` command is probably better. In the GLM approach, you specify `family(nbinomial #k)` and then search for a  $\#_k$  that results in the deviance-based dispersion being 1. You can also specify `family(nbinomial ml)` to estimate  $\#_k$  via maximum likelihood, which will report the same value returned from `nbreg`. However, `nbreg` also reports a confidence interval for it; see [R] [nbreg](#) and Rogers (1993). Of course, `glm` allows links other than `log`, and for those links, including the canonical `nbinomial` link, you will need to use `glm`.
5. `glm` can be used to estimate parameters from exponential regressions, but this method requires specifying `scale(1)`. However, censoring is not available. Censored exponential regression may be modeled using `glm` with `family(poisson)`. The log of the original response is entered into a Poisson model as an offset, whereas the new response is the censor variable. The result of such modeling is identical to the log relative hazard parameterization of `streg`, `dist(exp) nohr`. See [ST] [streg](#) for details about the `streg` command.

In general, where there is overlap between a capability of `glm` and that of some other Stata command, we recommend using the other Stata command. Our recommendation is not because of some inferiority of the GLM approach. Rather, those other commands, by being specialized, provide options and ancillary commands that are missing in the broader `glm` framework. Nevertheless, `glm` does produce the same answers where it should.

*Special note.* When equivalence is expected, for some datasets, you may still see very slight differences in the results, most often only in the later digits of the standard errors. When you compare `glm` output to an equivalent Stata command, these tiny discrepancies arise for many reasons:

- a. `glm` uses a general methodology for starting values, whereas the equivalent Stata command may be more specialized in its treatment of starting values.
- b. When using a canonical link, `glm`, `irls` should be equivalent to the maximum likelihood method of the equivalent Stata command, yet the convergence criterion is different (one is for deviance, the other for log likelihood). These discrepancies are easily resolved by adjusting one convergence criterion to correspond to the other.

- c. When both `glm` and the equivalent Stata command use Newton–Raphson, small differences may still occur if the Stata command has a different default convergence criterion from that of `glm`. Adjusting the convergence criterion will resolve the difference. See [R] `ml` and [R] `Maximize` for more details. □

### ▷ Example 1

In [example 1](#) of [R] `logistic`, we fit a model based on data from a study of risk factors associated with low birthweight (Hosmer, Lemeshow, and Sturdivant 2013, 24). We can replicate the estimation by using `glm`:

```
. use https://www.stata-press.com/data/r19/lbw
(Hosmer & Lemeshow data)
. glm low age lwt i.race smoke ptl ht ui, family(binomial) link(logit)
Iteration 0: Log likelihood = -101.0213
Iteration 1: Log likelihood = -100.72519
Iteration 2: Log likelihood = -100.724
Iteration 3: Log likelihood = -100.724

Generalized linear models Number of obs = 189
Optimization : ML Residual df = 180
 Scale parameter = 1
Deviance = 201.4479911 (1/df) Deviance = 1.119156
Pearson = 182.0233425 (1/df) Pearson = 1.011241
Variance function: V(u) = u*(1-u) [Bernoulli]
Link function : g(u) = ln(u/(1-u)) [Logit]
Log likelihood = -100.7239956 AIC = 1.1611
 BIC = -742.0665
```

| low   | OIM         |           | z     | P> z  | [95% conf. interval] |           |

| ui    | 2.1351     | .9808153  | 1.65  | 0.099 | .8677528             | 5.2534   |
| _cons | 1.586014   | 1.910496  | 0.38  | 0.702 | .1496092             | 16.8134  |

Note: `_cons` estimates baseline odds.

These results are the same as those reported in [example 1](#) of [\[R\] logistic](#).

Included in the output header are values for the [Akaike \(1973\)](#) information criterion (AIC) and the Bayesian information criterion (BIC) ([Raftery 1995](#)). Both are measures of model fit adjusted for the number of parameters that can be compared across models. In both cases, a smaller value generally indicates a better model fit. AIC is based on the log likelihood and thus is available only when Newton–Raphson optimization is used. BIC is based on the deviance and thus is always available.

### □ Technical note

The values for AIC and BIC reported in the output after `glm` are different from those reported by `estat ic`:

```
. estat ic
Akaike's information criterion and Bayesian information criterion
```

| Model | N   | ll(null) | ll(model) | df | AIC     | BIC      |
|-------|-----|----------|-----------|----|---------|----------|
| .     | 189 | .        | -100.724  | 9  | 219.448 | 248.6237 |

Note: BIC uses N = number of observations. See [\[R\] IC note](#).

There are various definitions of these information criteria (IC) in the literature; `glm` and `estat ic` use different definitions. `glm` bases its computation of the BIC on deviance, whereas `estat ic` uses the likelihood. Both `glm` and `estat ic` use the likelihood to compute the AIC; however, the AIC from `estat ic` is equal to  $N$ , the number of observations, times the AIC from `glm`. Refer to [Methods and formulas](#) in this entry and [\[R\] estat ic](#) for the references and formulas used by `glm` and `estat ic`, respectively, to compute AIC and BIC. Inferences based on comparison of IC values reported by `glm` for different GLM models will be equivalent to those based on comparison of IC values reported by `estat ic` after `glm`. □

## ▷ Example 2

We use data from an early insecticide experiment, given in [Pregibon \(1980\)](#). The variables are `ldose`, the log dose of insecticide; `n`, the number of flour beetles subjected to each dose; and `r`, the number killed.

```
. use https://www.stata-press.com/data/r19/ldose
. list, sep(4)
```

|    | ldose  | n  | r  |
|----|--------|----|----|
| 1. | 1.6907 | 59 | 6  |
| 2. | 1.7242 | 60 | 13 |
| 3. | 1.7552 | 62 | 18 |
| 4. | 1.7842 | 56 | 28 |
| 5. | 1.8113 | 63 | 52 |
| 6. | 1.8369 | 59 | 53 |
| 7. | 1.861  | 62 | 61 |
| 8. | 1.8839 | 60 | 60 |

The aim of the analysis is to estimate a dose–response relationship between  $p$ , the proportion killed, and  $X$ , the log dose.

As a first attempt, we will formulate the model as a linear logistic regression of  $p$  on `ldose`; that is, we will take the logit of  $p$  and represent the dose–response curve as a straight line in  $X$ :

$$\ln\{p/(1-p)\} = \beta_0 + \beta_1 X$$

Because the data are grouped, we cannot use Stata's logistic command to fit the model. Instead, we will fit the model by using glm:

```
. glm r ldose, family(binomial n) link(logit)
Iteration 0: Log likelihood = -18.824848
Iteration 1: Log likelihood = -18.715271
Iteration 2: Log likelihood = -18.715123
Iteration 3: Log likelihood = -18.715123

Generalized linear models Number of obs = 8
Optimization : ML Residual df = 6
 Scale parameter = 1
Deviance = 11.23220702 (1/df) Deviance = 1.872035
Pearson = 10.0267936 (1/df) Pearson = 1.671132

Variance function: V(u) = u*(1-u/n) [Binomial]
Link function : g(u) = ln(u/(n-u)) [Logit]

Log likelihood = -18.71512262 AIC = 5.178781
 BIC = -1.244442
```

| r     | OIM         |           |        |       |                      |
|-------|-------------|-----------|--------|-------|----------------------|
|       | Coefficient | std. err. | z      | P> z  | [95% conf. interval] |
| ldose | 34.27034    | 2.912141  | 11.77  | 0.000 | 28.56265 39.97803    |
| _cons | -60.71747   | 5.180713  | -11.72 | 0.000 | -70.87149 -50.56346  |

We specified family(binomial n), meaning that variable n contains the denominator.

An alternative model, which gives asymmetric sigmoid curves for p, involves the complementary log–log, or cloglog, function:

$$\ln\{-\ln(1-p)\} = \beta_0 + \beta_1 X$$

We fit this model by using glm:

```
. glm r ldose, family(binomial n) link(cloglog)
Iteration 0: Log likelihood = -14.883594
Iteration 1: Log likelihood = -14.822264
Iteration 2: Log likelihood = -14.822228
Iteration 3: Log likelihood = -14.822228

Generalized linear models Number of obs = 8
Optimization : ML Residual df = 6
 Scale parameter = 1
Deviance = 3.446418004 (1/df) Deviance = .574403
Pearson = 3.294675153 (1/df) Pearson = .5491125

Variance function: V(u) = u*(1-u/n) [Binomial]
Link function : g(u) = ln(-ln(1-u/n)) [Complementary log-log]

Log likelihood = -14.82222811 AIC = 4.205557
 BIC = -9.030231
```

| r     | OIM         |           |        |       |                      |
|-------|-------------|-----------|--------|-------|----------------------|
|       | Coefficient | std. err. | z      | P> z  | [95% conf. interval] |
| ldose | 22.04118    | 1.793089  | 12.29  | 0.000 | 18.52679 25.55557    |
| _cons | -39.57232   | 3.229047  | -12.26 | 0.000 | -45.90114 -33.24351  |

The cloglog model is preferred; the deviance for the logistic model, 11.23, is much higher than the deviance for the cloglog model, 3.45. This change also is evident by comparing log likelihoods, or equivalently, AIC values.

This example also shows the advantage of the `glm` command—we can vary assumptions easily. Note the minor difference in what we typed to obtain the logistic and cloglog models:

```
. glm r ldose, family(binomial n) link(logit)
. glm r ldose, family(binomial n) link(cloglog)
```

If we were performing this work for ourselves, we would have typed the commands in a more abbreviated form:

```
. glm r ldose, f(b n) l(1)
. glm r ldose, f(b n) l(c1)
```

◀

## □ Technical note

Factor variables may be used with `glm`. Say that, in the [example above](#), we had `ldose`, the log dose of insecticide; `n`, the number of flour beetles subjected to each dose; and `r`, the number killed—all as before—except that now we have results for three different kinds of beetles. Our hypothetical data include `beetle`, which contains the values 1 (“Destructive flour”), 2 (“Red flour”), and 3 (“Mealworm”).

```
. use https://www.stata-press.com/data/r19/beetle
. list, sep(0)
```

|     | beetle                  | ldose  | n  | r  |
|-----|-------------------------|--------|----|----|
| 1.  | Destructive flour       | 1.6907 | 59 | 6  |
| 2.  | Destructive flour       | 1.7242 | 60 | 13 |
| 3.  | Destructive flour       | 1.7552 | 62 | 18 |
| 4.  | Destructive flour       | 1.7842 | 56 | 28 |
| 5.  | Destructive flour       | 1.8113 | 63 | 52 |
|     | <i>(output omitted)</i> |        |    |    |
| 23. | Mealworm                | 1.861  | 64 | 23 |
| 24. | Mealworm                | 1.8839 | 58 | 22 |

Let's assume that, at first, we wish merely to add a shift factor for the type of beetle. We could type

```
. glm r i.beetle ldose, family(bin n) link(cloglog)
Iteration 0: Log likelihood = -79.012269
Iteration 1: Log likelihood = -76.94951
Iteration 2: Log likelihood = -76.945645
Iteration 3: Log likelihood = -76.945645

Generalized linear models Number of obs = 24
Optimization : ML Residual df = 20
 Scale parameter = 1
Deviance = 73.76505595 (1/df) Deviance = 3.688253
Pearson = 71.8901173 (1/df) Pearson = 3.594506

Variance function: V(u) = u*(1-u/n) [Binomial]
Link function : g(u) = ln(-ln(1-u/n)) [Complementary log-log]

Log likelihood = -76.94564525 AIC = 6.74547
 BIC = 10.20398
```

| r         | OIM         |           | z      | P> z  | [95% conf. interval] |           |
|-----------|-------------|-----------|--------|-------|----------------------|-----------|
|           | Coefficient | std. err. |        |       |                      |           |
| beetle    |             |           |        |       |                      |           |
| Red flour | -.0910396   | .1076132  | -0.85  | 0.398 | -.3019576            | .1198783  |
| Mealworm  | -1.836058   | .1307125  | -14.05 | 0.000 | -2.09225             | -1.579867 |
| ldose     | 19.41558    | .9954265  | 19.50  | 0.000 | 17.46458             | 21.36658  |
| _cons     | -34.84602   | 1.79333   | -19.43 | 0.000 | -38.36089            | -31.33116 |

We find strong evidence that the insecticide works differently on the mealworm. We now check whether the curve is merely shifted or also differently sloped:

```
. glm r beetle#c.ldose, family(bin n) link(cloglog)
Iteration 0: Log likelihood = -67.270188
Iteration 1: Log likelihood = -65.149316
Iteration 2: Log likelihood = -65.147978
Iteration 3: Log likelihood = -65.147978

Generalized linear models Number of obs = 24
Optimization : ML Residual df = 18
 Scale parameter = 1
Deviance = 50.16972096 (1/df) Deviance = 2.787207
Pearson = 49.28422567 (1/df) Pearson = 2.738013

Variance function: V(u) = u*(1-u/n) [Binomial]
Link function : g(u) = ln(-ln(1-u/n)) [Complementary log-log]

Log likelihood = -65.14797776 AIC = 5.928998
 BIC = -7.035248
```

| r              | OIM         |           |        |       |                      |           |
|----------------|-------------|-----------|--------|-------|----------------------|-----------|
|                | Coefficient | std. err. | z      | P> z  | [95% conf. interval] |           |
| beetle         |             |           |        |       |                      |           |
| Red flour      | -.79933     | 4.470882  | -0.18  | 0.858 | -9.562098            | 7.963438  |
| Mealworm       | 17.78741    | 4.586429  | 3.88   | 0.000 | 8.798172             | 26.77664  |
| ldose          | 22.04118    | 1.793089  | 12.29  | 0.000 | 18.52679             | 25.55557  |
| beetle#c.ldose |             |           |        |       |                      |           |
| Red flour      | .3838708    | 2.478477  | 0.15   | 0.877 | -4.473855            | 5.241596  |
| Mealworm       | -10.726     | 2.526412  | -4.25  | 0.000 | -15.67768            | -5.774321 |
| _cons          | -39.57232   | 3.229047  | -12.26 | 0.000 | -45.90114            | -33.24351 |

We find that the (complementary log–log) dose–response curve for the mealworm has roughly half the slope of that for the destructive flour beetle.

See [U] 26 [Working with categorical data and factor variables](#); what is said there concerning linear regression is applicable to any GLM model.

□

## Variance estimators

glm offers many variance options and gives different types of standard errors when used in various combinations. We highlight some of them here, but for a full explanation, see [Hardin and Hilbe \(2018\)](#).

### ▷ Example 3

Continuing with our flour beetle data, we rerun the most recently displayed model, this time requesting estimation via IRLS.

```
. use https://www.stata-press.com/data/r19/beetle
. glm r beetle#c.ldose, f(bin n) l(cloglog) ltol(1e-13) irls
Iteration 1: Deviance = 54.41414

Note our use of the `ltol()` option, which, although unrelated to our discussion on variance estimation, was used so that the regression coefficients would match those of the previous Newton–Raphson (NR) fit.

Because IRLS uses the EIM for optimization, the variance estimate is also based on EIM. If we want optimization via IRLS but the variance estimate based on OIM, we specify `glm, irls vce(oim)`:

```
. glm r beetle#c.ldose, f(b n) l(c1) ltol(1e-15) irls vce(oim) noheader nolog
```

| r              | OIM         |           |        |       |                      |           |
|----------------|-------------|-----------|--------|-------|----------------------|-----------|
|                | Coefficient | std. err. | z      | P> z  | [95% conf. interval] |           |
| beetle         |             |           |        |       |                      |           |
| Red flour      | -.79933     | 4.470882  | -0.18  | 0.858 | -9.562098            | 7.963438  |
| Mealworm       | 17.78741    | 4.586429  | 3.88   | 0.000 | 8.798172             | 26.77664  |
| ldose          | 22.04118    | 1.793089  | 12.29  | 0.000 | 18.52679             | 25.55557  |
| beetle#c.ldose |             |           |        |       |                      |           |
| Red flour      | .3838708    | 2.478477  | 0.15   | 0.877 | -4.473855            | 5.241596  |
| Mealworm       | -10.726     | 2.526412  | -4.25  | 0.000 | -15.67768            | -5.774321 |
| _cons          | -39.57232   | 3.229047  | -12.26 | 0.000 | -45.90114            | -33.24351 |

This approach is identical to NR except for the convergence path. Because the cloglog link is not the canonical link for the binomial family, EIM and OIM produce different results. Both estimators, however, are asymptotically equivalent.

Going back to NR, we can also specify `vce(robust)` to get the Huber/White/sandwich estimator of variance:

```
. glm r beetle#c.ldose, f(b n) l(c1) vce(robust) noheader nolog
```

| r              | Robust      |           |        |       |                      |           |
|----------------|-------------|-----------|--------|-------|----------------------|-----------|
|                | Coefficient | std. err. | z      | P> z  | [95% conf. interval] |           |
| beetle         |             |           |        |       |                      |           |
| Red flour      | -.79933     | 5.733049  | -0.14  | 0.889 | -12.0359             | 10.43724  |
| Mealworm       | 17.78741    | 5.158477  | 3.45   | 0.001 | 7.676977             | 27.89784  |
| ldose          | 22.04118    | .8998551  | 24.49  | 0.000 | 20.27749             | 23.80486  |
| beetle#c.ldose |             |           |        |       |                      |           |
| Red flour      | .3838708    | 3.174427  | 0.12   | 0.904 | -5.837892            | 6.605633  |
| Mealworm       | -10.726     | 2.800606  | -3.83  | 0.000 | -16.21508            | -5.236912 |
| _cons          | -39.57232   | 1.621306  | -24.41 | 0.000 | -42.75003            | -36.39462 |

The sandwich estimator gets its name from the form of the calculation—it is the multiplication of three matrices, with the outer two matrices (the “bread”) set to the OIM variance matrix. When `irls` is used along with `vce(robust)`, the EIM variance matrix is instead used as the bread. Using a result from [McCullagh and Nelder \(1989\)](#), [Newson \(1999\)](#) points out that the EIM and OIM variance matrices are equivalent under the canonical link. Thus if `irls` is specified with the canonical link, the resulting variance is labeled “Robust”. When the noncanonical link for the family is used, which is the case in the example below, the EIM and OIM variance matrices differ, so the resulting variance is labeled “Semirobust”.

```
. glm r beetle##c.ldose, f(b n) l(c1) irls ltol(1e-15) vce(robust) noheader
> nolog
```

| r              | Semirobust  |           | z      | P> z  | [95% conf. interval] |           |
|----------------|-------------|-----------|--------|-------|----------------------|-----------|
|                | Coefficient | std. err. |        |       |                      |           |
| beetle         |             |           |        |       |                      |           |
| Red flour      | -.79933     | 6.288963  | -0.13  | 0.899 | -13.12547            | 11.52681  |
| Mealworm       | 17.78741    | 5.255307  | 3.38   | 0.001 | 7.487194             | 28.08762  |

The outer product of the gradient (OPG) estimate of variance is one that avoids the calculation of second derivatives. It is equivalent to the “middle” part of the sandwich estimate of variance and can be specified by using `glm, vce(opg)`, regardless of whether NR or IRLS optimization is used.

```
. glm r beetle##c.ldose, f(b n) l(c1) vce(opg) noheader nolog
```

| r              | OPG         |           | z     | P> z  | [95% conf. interval] |           |

|                | Coefficient | std. err. |       |       |                      |           |
| beetle         |             |           |       |       |                      |           |
| Red flour      | -.79933     | 6.664045  | -0.12 | 0.905 | -13.86062            | 12.26196  |
| Mealworm       | 17.78741    | 6.838505  | 2.60  | 0.009 | 4.384183             | 31.19063  |
| ldose          | 22.04118    | 3.572983  | 6.17  | 0.000 | 15.03826             | 29.0441   |
| beetle#c.ldose |             |           |       |       |                      |           |
| Red flour      | .3838708    | 3.700192  | 0.10  | 0.917 | -6.868372            | 7.636114  |
| Mealworm       | -10.726     | 3.796448  | -2.83 | 0.005 | -18.1669             | -3.285097 |
| _cons          | -39.57232   | 6.433101  | -6.15 | 0.000 | -52.18097            | -26.96368 |

The OPG estimate of variance is a component of the BHHH (Berndt et al. 1974) optimization technique. This method of optimization is also available with `glm` with the `technique()` option; however, the `technique()` option is not allowed with the `irls` option.

#### ▷ Example 4

The Newey–West (1987) estimator of variance is a sandwich estimator with the “middle” of the sandwich modified to account for possible autocorrelation between the observations. These estimators are a generalization of those given by the Stata command `newey` for linear regression. See [TS] [newey](#) for more details.

For example, consider the dataset given in [TS] `newey`, which has time-series measurements on `usr` and `idle`. We want to perform a linear regression with Newey–West standard errors.

```
. use https://www.stata-press.com/data/r19/idle2
. list usr idle time
```

|                  | usr | idle | time |
|------------------|-----|------|------|
| 1.               | 0   | 100  | 1    |
| 2.               | 0   | 100  | 2    |
| 3.               | 0   | 97   | 3    |
| 4.               | 1   | 98   | 4    |
| 5.               | 2   | 94   | 5    |
| (output omitted) |     |      |      |
| 29.              | 1   | 98   | 29   |
| 30.              | 1   | 98   | 30   |

Examining *Methods and formulas* of [TS] `newey`, we see that the variance estimate is multiplied by a correction factor of  $n/(n - k)$ , where  $k$  is the number of regressors. `glm, vce(hac ...)` does not make this correction, so to get the same standard errors, we must use the `vfactor()` option within `glm` to make the correction manually.

```
. display 30/28
1.0714286
. tsset time
Time variable: time, 1 to 30
 Delta: 1 unit
. glm usr idle, vce(hac nwest 3) vfactor(1.0714286)
Iteration 0: Log likelihood = -71.743396
Generalized linear models Number of obs = 30
Optimization : ML Residual df = 28
 Scale parameter = 7.493297
Deviance = 209.8123165 (1/df) Deviance = 7.493297
Pearson = 209.8123165 (1/df) Pearson = 7.493297
Variance function: V(u) = 1 [Gaussian]
Link function : g(u) = u [Identity]
HAC kernel (lags): Newey-West (3)
Log likelihood = -71.74339627 AIC = 4.916226
 BIC = 114.5788
```

| usr   | HAC         |           |       | z     | P> z      | [95% conf. interval] |  |
|-------|-------------|-----------|-------|-------|-----------|----------------------|--|
|       | Coefficient | std. err. |       |       |           |                      |  |
| idle  | -.2281501   | .0690928  | -3.30 | 0.001 | -.3635694 | -.0927307            |  |

| idle  | -.0796609   | .0184647  | -4.31 | 0.000 | -.115851             | -.0434708 |
| _cons | 7.771011    | 1.510198  | 5.15  | 0.000 | 4.811078             | 10.73094  |

glm also offers variance estimators based on the bootstrap (resampling your data with replacement) and the jackknife (refitting the model with each observation left out in succession). Also included is the one-step jackknife estimate, which, instead of performing full reestimation when each observation is omitted, calculates a one-step NR estimate, with the full data regression coefficients as starting values.

```
. set seed 1
. glm usr idle, fam(gamma) link(log) vce(bootstrap, reps(100) nodots)
Generalized linear models
Optimization : ML

| idle  | -.0796609   | .016657   | -4.78 | 0.000 | -.1123081    | -.0470137            |
| _cons | 7.771011    | 1.378037  | 5.64  | 0.000 | 5.070108     | 10.47192             |

See [Hardin and Hilbe \(2018\)](#) for a full discussion of the variance options that go with glm and, in particular, of how the different variance estimators are modified when vce(cluster *clustvar*) is specified. Finally, not all variance options are supported with all types of weights. See help glm for a current table of the variance options that are supported with the different weights.

## User-defined functions

glm may be called with a community-contributed link function, variance (family) function, Newey–West kernel-weight function, or any combination of the three.

### Syntax of link functions

```

program programe
version 19.5 // (or version 19 if you do not have StataNow)
args todo eta mu return

if `todo' == -1 {
 /* Set global macros for output */
 global SGLM_lt "title for link function"
 global SGLM_lf "subtitle showing link definition"
 exit
}
if `todo' == 0 {
 /* set $\eta = g(\mu)$ */
 /* Intermediate calculations go here */
 generate double `eta' = ...
 exit
}
if `todo' == 1 {
 /* set $\mu = g^{-1}(\eta)$ */
 /* Intermediate calculations go here */
 generate double `mu' = ...
 exit
}
if `todo' == 2 {
 /* set return= $\partial\mu/\partial\eta$ */
 /* Intermediate calculations go here */
 generate double `return' = ...
 exit
}
if `todo' == 3 {
 /* set return= $\partial^2\mu/\partial\eta^2$ */
 /* Intermediate calculations go here */
 generate double `return' = ...
 exit
}
display as error "Unknown call to glm link function"
exit 198
end

```

## Syntax of variance functions

```

program programe
 version 19.5 // (or version 19 if you do not have StataNow)
 args todo eta mu return

 if `todo' == -1 {
 /* Set global macros for output */
 /* Also check that devar is in proper range */
 /* Note: For this call, eta contains indicator for whether each obs. is in est. sample */
 global SGLM_vt "title for variance function"
 global SGLM_vf "subtitle showing function definition"
 global SGLM_mu "program to call to enforce boundary conditions on μ "
 exit
 }
 if `todo' == 0 {
 /* set η to initial value. */
 /* Intermediate calculations go here */
 generate double `eta' = ...
 exit
 }
 if `todo' == 1 {
 /* set return = $V(\mu)$ */
 /* Intermediate calculations go here */
 generate double `return' = ...
 exit
 }
 if `todo' == 2 {
 /* set return = $\partial V(\mu)/\partial \mu$ */
 /* Intermediate calculations go here */
 generate double `return' = ...
 exit
 }

## Syntax of Newey–West kernel-weight functions

```

program progrname, rclass
 version 19.5 // (or version 19 if you do not have StataNow)
 args G j
 /* G is the maximum lag */
 /* j is the current lag */

 /* Intermediate calculations go here */

 return scalar wt = computed weight
 return local setype "Newey-West"
 return local sewtype "name of kernel"
end

```

## Global macros available for community-contributed programs

| Global macro | Description                                                                                                        |
|--------------|--------------------------------------------------------------------------------------------------------------------|
| SGLM_V       | program name of variance (family) evaluator                                                                        |
| SGLM_L       | program name of link evaluator                                                                                     |
| SGLM_y       | dependent variable name                                                                                            |
| SGLM_m       | binomial denominator                                                                                               |
| SGLM_a       | negative binomial $k$                                                                                              |
| SGLM_p       | power if <code>power()</code> or <code>opower()</code> is used, or an argument from a user-specified link function |
| SGLM_s1      | indicator; set to one if scale is equal to one                                                                     |
| SGLM_ph      | value of scale parameter                                                                                           |

### ▷ Example 5

Suppose that we wish to perform Poisson regression with a log-link function. Although this regression is already possible with standard `glm`, we will write our own version for illustrative purposes.

Because we want a log link,  $\eta = g(\mu) = \ln(\mu)$ , and for a Poisson family the variance function is  $V(\mu) = \mu$ .

The Poisson density is given by

$$f(y_i) = \frac{e^{-\exp(\mu_i)} e^{\mu_i y_i}}{y_i!}$$

resulting in a log likelihood of

$$L = \sum_{i=1}^n \{-e^{\mu_i} + \mu_i y_i - \ln(y_i!)\}$$

The squared deviance of the  $i$ th observation for the Poisson family is given by

$$d_i^2 = \begin{cases} 2\hat{\mu}_i & \text{if } y_i = 0 \\ 2\{y_i \ln(y_i/\hat{\mu}_i) - (y_i - \hat{\mu}_i)\} & \text{otherwise} \end{cases}$$

We now have enough information to write our own Poisson-log glm module. We create the file `mylog.ado`, which contains

```

program mylog
 version 19.5 // (or version 19 if you do not have StataNow)
 args todo eta mu return

 if `todo' == -1 {
 global SGLM_lt "My Log" // Titles for output
 global SGLM_lf "ln(u)"
 exit
 }
 if `todo' == 0 {
 gen double `eta' = ln(`mu') // $\eta = \ln(\mu)$
 exit
 }
 if `todo' == 1 {
 gen double `mu' = exp(`eta') // $\mu = \exp(\eta)$
 exit
 }
 if `todo' == 2 {
 gen double `return' = `mu' // $\partial\mu/\partial\eta = \exp(\eta) = \mu$
 exit
 }
 if `todo' == 3 {
 gen double `return' = `mu' // $\partial^2\mu/\partial\eta^2 = \exp(\eta) = \mu$
 exit
 }
 di as error "Unknown call to glm link function"
 exit 198
end

```

and we create the file `mypoiso.ado`, which contains

```

program mypoiso
 version 19.5 // (or version 19 if you do not have StataNow)
 args todo eta mu return

 if `todo' == -1 {
 local y "$SGLM_y"
 local touse "`eta'"
 capture assert `y'>=0 if `touse' // check range of y
 if _rc {
 di as error "'dependent variable `y' has negative values'"
 exit 499
 }
 global SGLM_vt "My Poisson" // Titles for output
 global SGLM_vf "u"
 global SGLM_mu "glim_mu 0 ." // see note 1
 exit
 }
 if `todo' == 0 {
 gen double `eta' = ln(`mu') // Initialization of η ; see note 2
 exit
 }

```

```

if `todo' == 1 {
 gen double `return' = `mu' // $V(\mu) = \mu$
 exit
}
if `todo' == 2 {
 gen byte `return' = 1 // $\partial V(\mu)/\partial \mu$
 exit
}
if `todo' == 3 {
 local y "$SGLM_y"
 if "`y'" == "" {
 local y "e(depvar)"
 }
 gen double `return' = cond(`y'==0, 2*`mu', /*
 / 2(`y'*ln(`y'/`mu')-(`y'-`mu'))
 exit
}
if `todo' == 4 {
 local y "$SGLM_y"
 if "`y'" == "" {
 local y "e(depvar)"
 }
 gen double `return' = 1.5*(`y'^(2/3)-`mu'^(2/3)) / `mu'^(1/6)
 exit
}
if `todo' == 5 {
 local y "$SGLM_y"
 if "`y'" == "" {
 local y "e(depvar)"
 }
 gen double `return' = -`mu'+`y'*ln(`mu')-lngamma(`y'+1)
 exit
}
if `todo' == 6 {
 gen double `return' = 1/(6*sqrt(`mu')) // adjustment to residual; see note 5
 exit
}
di as error "Unknown call to glm variance function"
error 198
end

```

## Notes:

1. `glm_mu` is a Stata program that will, at each iteration, bring  $\hat{\mu}$  back into its plausible range, should it stray out of it. Here `glm_mu` is called with the arguments zero and missing, meaning that zero is the lower bound of  $\hat{\mu}$  and there exists no upper bound—such is the case for Poisson models.
2. Here the initial value of  $\eta$  is easy because we intend to fit this model with our user-defined log link. In general, however, the initialization may need to vary according to the link to obtain convergence. If so, the global macro `SGLM_L` is used to determine which link is being utilized.
3. The Anscombe formula is given here because we know it. If we were not interested in Anscombe residuals, we could merely set ``return'` to missing. Also, the local macro `y` is set either to `SGLM_y` if it is in current estimation or to `e(depvar)` if this function is being accessed by `predict`.
4. If we were not interested in ML estimation, we could omit this code entirely and just leave an `exit` statement in its place. Similarly, if we were not interested in deviance or IRLS optimization, we could set ``return'` in the deviance portion of the code (``todo'==3`) to missing.

5. This code defines the term to be added to the predicted residuals if the adjusted option is specified. Again, if we were not interested, we could set 'return' to missing.

We can now test our Poisson-log module by running it on the airline data presented in [R] poisson.

```
. use https://www.stata-press.com/data/r19/airline
. list airline injuries n XYZowned
```

|    | airline | injuries | n      | XYZowned |
|----|---------|----------|--------|----------|
| 1. | 1       | 11       | 0.0950 | 1        |
| 2. | 2       | 7        | 0.1920 | 0        |
| 3. | 3       | 7        | 0.0750 | 0        |
| 4. | 4       | 19       | 0.2078 | 0        |
| 5. | 5       | 9        | 0.1382 | 0        |
| 6. | 6       | 4        | 0.0540 | 1        |
| 7. | 7       | 3        | 0.1292 | 0        |
| 8. | 8       | 1        | 0.0503 | 0        |
| 9. | 9       | 3        | 0.0629 | 1        |

```

(Standard errors scaled using dispersion equal to square root of 1.)

These are precisely the results given in [R] poisson and are those that would have been given had we run glm, family(poisson) link(log). The only minor adjustment we needed to make was to specify the scale(1) option. If scale() is left unspecified, glm assumes scale(1) for discrete distributions and scale(x2) for continuous ones. By default, glm assumes that any user-defined family is continuous because it has no way of checking. Thus, we needed to specify scale(1) because our model is discrete.

Because we were careful in defining the squared deviance, we could have fit this model with IRLS. Because log is the canonical link for the Poisson family, we would not only get the same regression coefficients but also the same standard errors.

## ▶ Example 6

Suppose now that we wish to use our log link (`mylog.ado`) with `glm`'s binomial family. This task requires some modification because our current function is not equipped to deal with the binomial denominator, which we are allowed to specify. This denominator is accessible to our link function through the global macro `SGLM_m`. We now make the modifications and store them in `mylog2.ado`.

```

program mylog2 // <-- changed
version 19.5 // (or version 19 if you do not have StataNow)
args todo eta mu return
if 'todo' == -1 {
 global SGLM_lt "My Log, Version 2" // <-- changed
 if "$SGLM_m" == "1" { // <-- changed
 global SGLM_lf "ln(u)" // <-- changed
 } // <-- changed
 else global SGLM_lf "ln(u/$SGLM_m)" // <-- changed
 exit
}
if 'todo' == 0 {
 gen double 'eta' = ln('mu'/$SGLM_m) // <-- changed
 exit
}
if 'todo' == 1 {
 gen double 'mu' = $SGLM_m*exp('eta') // <-- changed
 exit
}
if 'todo' == 2 {
 gen double 'return' = 'mu'
 exit
}
if 'todo' == 3 {
 gen double 'return' = 'mu'
 exit
}
di as error "Unknown call to glm link function"
exit 198
end

```

We can now run our new log link with `glm`'s binomial family. Using the flour beetle data from earlier, we have

```

. use https://www.stata-press.com/data/r19/beetle, clear
. glm r ldose, f(bin n) l(mylog2) irls

Iteration 1: Deviance = 2212.108

◀

For a more detailed discussion on user-defined functions, and for an example of a user-defined Newey–West kernel weight, see [Hardin and Hilbe \(2018\)](#).

John Ashworth Nelder (1924–2010) was born in Somerset, England. He studied mathematics and statistics at Cambridge and worked as a statistician at the National Vegetable Research Station and then Rothamsted Experimental Station. In retirement, he was actively affiliated with Imperial College London. Nelder was especially well known for his contributions to the theory of linear models and to statistical computing. He was the principal architect of generalized and hierarchical generalized linear models and of the programs GenStat and GLIM.

Robert William Maclagan Wedderburn (1947–1975) was born in Edinburgh and studied mathematics and statistics at Cambridge. At Rothamsted Experimental Station, he developed the theory of generalized linear models with Nelder and originated the concept of quaslikelihood. He died of anaphylactic shock from an insect bite on a canal holiday.

## Stored results

`glm`, `ml` stores the following in `e()`:

| e(asobserved)   | factor variables fvset as asobserved                                     |

## Matrices

|                 |                                              |
|-----------------|----------------------------------------------|
| e(b)            | coefficient vector                           |
| e(Cns)          | constraints matrix                           |
| e(ilog)         | iteration log (up to 20 iterations)          |
| e(gradient)     | gradient vector                              |
| e(V)            | variance-covariance matrix of the estimators |
| e(V_modelbased) | model-based variance                         |

## Functions

|           |                         |
|-----------|-------------------------|
| e(sample) | marks estimation sample |
|-----------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|          |                                                                                                                            |
|----------|----------------------------------------------------------------------------------------------------------------------------|
| r(table) | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |
|----------|----------------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

`glm`, `irls` stores the following in `e()`:

## Scalars

|                |                                                                        |
|----------------|------------------------------------------------------------------------|
| e(N)           | number of observations                                                 |
| e(k)           | number of parameters                                                   |
| e(k_eq_model)  | number of equations in overall model test                              |
| e(df_m)        | model degrees of freedom                                               |
| e(df)          | residual degrees of freedom                                            |
| e(phi)         | scale parameter                                                        |
| e(disp)        | dispersion parameter                                                   |
| e(bic)         | model BIC                                                              |
| e(N_clust)     | number of clusters                                                     |
| e(deviance)    | deviance                                                               |
| e(deviance_s)  | scaled deviance                                                        |
| e(deviance_p)  | Pearson deviance                                                       |
| e(deviance_ps) | scaled Pearson deviance                                                |
| e(dispers)     | dispersion                                                             |
| e(dispers_s)   | scaled dispersion                                                      |
| e(dispers_p)   | Pearson dispersion                                                     |
| e(dispers_ps)  | scaled Pearson dispersion                                              |
| e(nbml)        | 1 if negative binomial parameter estimated via ML, 0 otherwise         |
| e(vf)          | factor set by <code>vfactor()</code> , 1 if not set                    |
| e(power)       | power set by <code>link(power #)</code> or <code>link(opower #)</code> |
| e(rank)        | rank of <code>e(V)</code>                                              |
| e(rc)          | return code                                                            |

## Macros

|            |                            |

| <code>e(sample)</code>       | marks estimation sample                            |

In addition to the above, the following is stored in `r()`:

|                       |                                                                                                                            |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|
| Matrices              |                                                                                                                            |
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

The canonical reference on GLM is [McCullagh and Nelder \(1989\)](#). The term “generalized linear model” is from [Nelder and Wedderburn \(1972\)](#). Many people use the acronym GLIM for GLM models because of the classic GLM software tool GLIM, by [Baker and Nelder \(1985\)](#). See [Dobson and Barnett \(2018\)](#) for a concise introduction and overview. See [Rabe-Hesketh and Everitt \(2007\)](#) for more examples of GLM using Stata. [Hoffmann \(2004\)](#) focuses on applying generalized linear models, using real-world datasets, along with interpreting computer output, which for the most part is obtained using Stata.

This discussion highlights the details of parameter estimation and predicted statistics. For a more detailed treatment, and for information on variance estimation, see [Hardin and Hilbe \(2018\)](#). `glm` supports estimation with survey data. For details on VCEs with survey data, see [\[SVY\] Variance estimation](#).

`glm` obtains results by IRLS, as described in [McCullagh and Nelder \(1989\)](#), or by maximum likelihood using Newton–Raphson. The implementation here, however, allows user-specified weights, which we denote as  $v_j$  for the  $j$ th observation. Let  $M$  be the number of “observations” ignoring weights. Define

$$w_j = \begin{cases} 1 & \text{if no weights are specified} \\ v_j & \text{if fweights or iweights are specified} \\ Mv_j/(\sum_k v_k) & \text{if aweights or pweights are specified} \end{cases}$$

The number of observations is then  $N = \sum_j w_j$  if `fweights` are specified and  $N = M$  otherwise. Each IRLS step is performed by `regress` using  $w_j$  as the weights.

Let  $d_j^2$  denote the squared deviance residual for the  $j$ th observation:

For the Gaussian family,  $d_j^2 = (y_j - \hat{\mu}_j)^2$ .

For the Bernoulli family (binomial with denominator 1),

$$d_j^2 = \begin{cases} -2\ln(1 - \hat{\mu}_j) & \text{if } y_j = 0 \\ -2\ln(\hat{\mu}_j) & \text{otherwise} \end{cases}$$

For the binomial family with denominator  $m_j$ ,

$$d_j^2 = \begin{cases} 2y_j\ln(y_j/\hat{\mu}_j) + 2(m_j - y_j)\ln\{(m_j - y_j)/(m_j - \hat{\mu}_j)\} & \text{if } 0 < y_j < m_j \\ 2m_j\ln\{m_j/(m_j - \hat{\mu}_j)\} & \text{if } y_j = 0 \\ 2y_j\ln(y_j/\hat{\mu}_j) & \text{if } y_j = m_j \end{cases}$$

For the Poisson family,

$$d_j^2 = \begin{cases} 2\hat{\mu}_j & \text{if } y_j = 0 \\ 2\{y_j\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)\} & \text{otherwise} \end{cases}$$

For the gamma family,  $d_j^2 = -2\{\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)/\hat{\mu}_j\}$ .

For the inverse Gaussian,  $d_j^2 = (y_j - \hat{\mu}_j)^2/(\hat{\mu}_j^2 y_j)$ .

For the negative binomial,

$$d_j^2 = \begin{cases} 2\ln(1 + k\hat{\mu}_j)/k & \text{if } y_j = 0 \\ 2y_j\ln(y_j/\hat{\mu}_j) - 2\{(1 + ky_j)/k\}\ln\{(1 + ky_j)/(1 + k\hat{\mu}_j)\} & \text{otherwise} \end{cases}$$

Let  $\phi = 1$  if the scale parameter is set to one; otherwise, define  $\phi = \hat{\phi}_0(n - k)/n$ , where  $\hat{\phi}_0$  is the estimated scale parameter and  $k$  is the number of covariates in the model (including intercept).

Let  $\ln L_j$  denote the log likelihood for the  $j$ th observation:

For the Gaussian family,

$$\ln L_j = -\frac{1}{2} \left[ \left\{ \frac{(y_j - \hat{\mu}_j)^2}{\phi} \right\} + \ln(2\pi\phi) \right]$$

For the binomial family with denominator  $m_j$  (Bernoulli if all  $m_j = 1$ ),

$$\ln L_j = \phi \times \begin{cases} \ln\{\Gamma(m_j + 1)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m_j - y_j + 1)\} & \text{if } 0 < y_j < m_j \\ \quad + (m_j - y_j) \ln(1 - \hat{\mu}_j/m_j) + y_j \ln(\hat{\mu}_j/m_j) & \\ m_j \ln(1 - \hat{\mu}_j/m_j) & \text{if } y_j = 0 \\ m_j \ln(\hat{\mu}_j/m_j) & \text{if } y_j = m_j \end{cases}$$

For the Poisson family,

$$\ln L_j = \phi [y_j \ln(\hat{\mu}_j) - \hat{\mu}_j - \ln\{\Gamma(y_j + 1)\}]$$

For the gamma family,  $\ln L_j = -y_j/\hat{\mu}_j + \ln(1/\hat{\mu}_j)$ .

For the inverse Gaussian,

$$\ln L_j = -\frac{1}{2} \left\{ \frac{(y_j - \hat{\mu}_j)^2}{y_j \hat{\mu}_j^2} + 3 \ln(y_j) + \ln(2\pi) \right\}$$

For the negative binomial (let  $m = 1/k$ ),

$$\ln L_j = \phi \left[ \ln\{\Gamma(m + y_j)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m)\} \right. \\ \left. - m \ln(1 + \hat{\mu}_j/m) + y_j \ln\{\hat{\mu}_j/(\hat{\mu}_j + m)\} \right]$$

The overall deviance reported by `glm` is  $D^2 = \sum_j w_j d_j^2$ . The dispersion of the deviance is  $D^2$  divided by the residual degrees of freedom.

The Akaike information criterion (AIC) and Bayesian information criterion (BIC) are given by

$$\text{AIC} = \frac{-2 \ln L + 2k}{N}$$

$$\text{BIC} = D^2 - (N - k) \ln(N)$$

where  $\ln L = \sum_j w_j \ln L_j$  is the overall log likelihood.

The Pearson deviance reported by `glm` is  $\sum_j w_j r_j^2$ . The corresponding Pearson dispersion is the Pearson deviance divided by the residual degrees of freedom. `glm` also calculates the scaled versions of all of these quantities by dividing by the estimated scale parameter.

## Acknowledgments

glm was written by James Hardin of the Arnold School of Public Health at the University of South Carolina and Joseph Hilbe (1944–2017) of Arizona State University, the coauthors of the Stata Press book *Generalized Linear Models and Extensions*. The previous version of this routine was written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*. The original version of this routine was published in Royston (1994). Royston’s work, in turn, was based on a prior implementation by Joseph Hilbe, first published in Hilbe (1993). Roger Newson wrote an early implementation (Newson 1999) of robust variance estimates for GLM. Parts of this entry are excerpts from Hardin and Hilbe (2018).

## Postestimation commands

The following postestimation commands are available after `glm`:

| Command                         | Description                                                                                                                             |
|---------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <a href="#">contrast</a>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| * <a href="#">estat ic</a>      | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <a href="#">estat summarize</a> | summary statistics for the estimation sample                                                                                            |
| <a href="#">estat vce</a>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <a href="#">estat (svy)</a>     | postestimation statistics for survey data                                                                                               |
| <a href="#">estimates</a>       | cataloging estimation results                                                                                                           |
| <a href="#">etable</a>          | table of estimation results                                                                                                             |
| † <a href="#">forecast</a>      | dynamic forecasts and simulations                                                                                                       |
| † <a href="#">hausman</a>       | Hausman's specification test                                                                                                            |
| <a href="#">lincom</a>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <a href="#">linktest</a>        | link test for model specification                                                                                                       |
| *† <a href="#">lrtest</a>       | likelihood-ratio test                                                                                                                   |
| <a href="#">margins</a>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <a href="#">marginsplot</a>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <a href="#">nlcom</a>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <a href="#">predict</a>         | predictions, residuals, influence statistics, and other diagnostic measures                                                             |
| <a href="#">predictnl</a>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <a href="#">pwcompare</a>       | pairwise comparisons of parameters                                                                                                      |
| <a href="#">suest</a>           | seemingly unrelated estimation                                                                                                          |
| <a href="#">test</a>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <a href="#">testnl</a>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*[estat ic](#) and [lrtest](#) are not appropriate after `glm`, `irls`.

†[forecast](#), [hausman](#), and [lrtest](#) are not appropriate with `svy` estimation results. [forecast](#) is also not appropriate with `mi` estimation results.

# predict

## Description for predict

predict creates a new variable containing predictions such as expected values, linear predictions, standard errors, residuals, Cook’s distance, diagonals of the “hat” matrix, weighted averages, differences between the observed and fitted outcomes, and equation-level scores.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic options]
```

| <i>statistic</i>  | Description                                                                    |
|-------------------|--------------------------------------------------------------------------------|
| Main              |                                                                                |
| <u>mu</u>         | expected value of $y$ ; the default                                            |
| <u>xb</u>         | linear prediction $\eta = \mathbf{x}_j\hat{\beta}$                             |
| <u>eta</u>        | synonym of <u>xb</u>                                                           |
| <u>stdp</u>       | standard error of the linear prediction                                        |
| <u>anscombe</u>   | <a href="#">Anscombe (1953)</a> residuals                                      |
| <u>cooksd</u>     | Cook’s distance                                                                |
| <u>deviance</u>   | deviance residuals                                                             |
| <u>hat</u>        | diagonals of the “hat” matrix                                                  |
| <u>likelihood</u> | a weighted average of standardized deviance and standardized Pearson residuals |
| <u>pearson</u>    | Pearson residuals                                                              |
| <u>response</u>   | differences between the observed and fitted outcomes                           |
| <u>score</u>      | first derivative of the log likelihood with respect to $\mathbf{x}_j\beta$     |
| <u>working</u>    | working residuals                                                              |

| <i>options</i>      | Description                                                                                 |
|---------------------|---------------------------------------------------------------------------------------------|
| Options             |                                                                                             |
| <u>nooffset</u>     | modify calculations to ignore offset variable                                               |
| <u>adjusted</u>     | adjust deviance residual to speed up convergence                                            |
| <u>standardized</u> | multiply residual by the factor $(1 - h)^{-1/2}$                                            |
| <u>studentized</u>  | multiply residual by one over the square root of the estimated scale parameter              |
| <u>modified</u>     | modify denominator of residual to be a reasonable estimate of the variance of <i>depvar</i> |

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

mu, xb, stdp, and score are the only statistics allowed with svy estimation results.

## Options for predict

## Main

`mu`, the default, specifies that `predict` calculate the expected value of  $y$ , equal to  $g^{-1}(\mathbf{x}\hat{\boldsymbol{\beta}})$  [ $ng^{-1}(\mathbf{x}\hat{\boldsymbol{\beta}})$  for the binomial family].

`xb` calculates the linear prediction  $\eta = \mathbf{x}\hat{\boldsymbol{\beta}}$ .

`eta` is a synonym for `xb`.

`stdp` calculates the standard error of the linear prediction.

`anscombe` calculates the [Anscombe \(1953\)](#) residuals to produce residuals that closely follow a normal distribution.

`cooks` calculates Cook's distance, which measures the aggregate change in the estimated coefficients when each observation is left out of the estimation.

`deviance` calculates the deviance residuals. Deviance residuals are recommended by [McCullagh and Nelder \(1989\)](#) and by others as having the best properties for examining the goodness of fit of a GLM. They are approximately normally distributed if the model is correct. They may be plotted against the fitted values or against a covariate to inspect the model's fit. Also see the `pearson` option below.

`hat` calculates the diagonals of the "hat" matrix, analogous to linear regression.

`likelihood` calculates a weighted average of standardized deviance and standardized Pearson residuals.

`pearson` calculates the Pearson residuals. Pearson residuals often have markedly skewed distributions for nonnormal family distributions. Also see the `deviance` option above.

`response` calculates the differences between the observed and fitted outcomes.

`score` calculates the equation-level score,  $\partial \ln L / \partial (\mathbf{x}_j \boldsymbol{\beta})$ .

`working` calculates the working residuals, which are response residuals weighted according to the derivative of the link function.

## Options

`nooffset` is relevant only if you specified `offset` (*varname*) for `glm`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j \mathbf{b}$  rather than as  $\mathbf{x}_j \mathbf{b} + \text{offset}_j$ .

`adjusted` adjusts the deviance residual to speed up the convergence to the limiting normal distribution. The adjustment deals with adding to the deviance residual a higher-order term that depends on the variance function family. This option is allowed only when `deviance` is specified.

`standardized` requests that the residual be multiplied by the factor  $(1-h)^{-1/2}$ , where  $h$  is the diagonal of the hat matrix. This operation is done to account for the correlation between *depvar* and its predicted value.

`studentized` requests that the residual be multiplied by one over the square root of the estimated scale parameter.

modified requests that the denominator of the residual be modified to be a reasonable estimate of the variance of *depyar*. The base residual is multiplied by the factor  $(k/w)^{-1/2}$ , where  $k$  is either one or the user-specified dispersion parameter and  $w$  is the specified weight (or one if left unspecified).

## margins

### Description for margins

`margins` estimates margins of response for expected values and linear predictions.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>  | Description                                      |
|-------------------|--------------------------------------------------|
| <u>mu</u>         | expected value of $y$ ; the default              |
| <u>xb</u>         | linear prediction $\eta = \mathbf{x}\hat{\beta}$ |
| <u>eta</u>        | synonym for <code>xb</code>                      |
| <u>stdp</u>       | not allowed with <code>margins</code>            |
| <u>anscombe</u>   | not allowed with <code>margins</code>            |
| <u>cooksd</u>     | not allowed with <code>margins</code>            |
| <u>deviance</u>   | not allowed with <code>margins</code>            |
| <u>hat</u>        | not allowed with <code>margins</code>            |
| <u>likelihood</u> | not allowed with <code>margins</code>            |
| <u>pearson</u>    | not allowed with <code>margins</code>            |
| <u>response</u>   | not allowed with <code>margins</code>            |
| <u>score</u>      | not allowed with <code>margins</code>            |
| <u>working</u>    | not allowed with <code>margins</code>            |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## Remarks and examples

Remarks are presented under the following headings:

*Predictions*

*Other postestimation commands*

## Predictions

### ▷ Example 1

After `glm` estimation, `predict` may be used to obtain various predictions based on the model. In [example 2](#) of [\[R\] glm](#), we mentioned that the complementary log–log link seemed to fit the data better than the logit link. Now, we go back and obtain the fitted values and deviance residuals:

```
. use https://www.stata-press.com/data/r19/ldose
. glm r ldose, family(binomial n) link(logit)
 (output omitted)
. predict mu_logit
(option mu assumed; predicted mean r)
. predict dr_logit, deviance
. quietly glm r ldose, f(binomial n) l(cloglog)
. predict mu_cl
(option mu assumed; predicted mean r)
. predict dr_cl, d
. format mu_logit dr_logit mu_cl dr_cl %9.5f
. list r mu_logit dr_logit mu_cl dr_cl, sep(4)
```

|    | r  | mu_logit | dr_logit | mu_cl    | dr_cl    |
|----|----|----------|----------|----------|----------|
| 1. | 6  | 3.45746  | 1.28368  | 5.58945  | 0.18057  |
| 2. | 13 | 9.84167  | 1.05969  | 11.28067 | 0.55773  |
| 3. | 18 | 22.45139 | -1.19611 | 20.95422 | -0.80330 |
| 4. | 28 | 33.89761 | -1.59412 | 30.36942 | -0.63439 |
| 5. | 52 | 50.09584 | 0.60614  | 47.77644 | 1.28883  |
| 6. | 53 | 53.29092 | -0.12716 | 54.14273 | -0.52366 |
| 7. | 61 | 59.22216 | 1.25107  | 61.11331 | -0.11878 |
| 8. | 60 | 58.74297 | 1.59398  | 59.94723 | 0.32495  |

In six of the eight cases,  $|\text{dr\_logit}| > |\text{dr\_cl}|$ . The above represents only one of the many available options for `predict`. See [Hardin and Hilbe \(2018\)](#) for a more in-depth examination.

## Other postestimation commands

### □ Technical note

After `glm` estimation, you may perform any of the postestimation commands that you would perform after any other kind of estimation in Stata; see [\[U\] 20 Estimation and postestimation commands](#). Below, we test the joint significance of all the interaction terms.

```
. use https://www.stata-press.com/data/r19/beetle, clear
. glm r beetle#c.ldose, family(binomial n) link(cloglog)
(output omitted)
. testparm i.beetle beetle#c.ldose
(1) [r]2.beetle = 0
(2) [r]3.beetle = 0
(3) [r]2.beetle#c.ldose = 0
(4) [r]3.beetle#c.ldose = 0
 chi2(4) = 249.69
 Prob > chi2 = 0.0000
```

If you wanted to print the variance–covariance matrix of the estimators, you would type `estat vce`.

If you use the `linktest` postestimation command, you must also specify the `family()` and `link()` options; see [R] [linktest](#).

□

## Methods and formulas

We follow the terminology used in *Methods and formulas* of [R] [glm](#).

The deviance residual calculated by `predict` following `glm` is  $r_j^D = \text{sign}(y_j - \hat{\mu}_j) \sqrt{d_j^2}$ .

The Pearson residual calculated by `predict` following `glm` is

$$r_j^P = \frac{y_j - \hat{\mu}_j}{\sqrt{V(\hat{\mu}_j)}}$$

where  $V(\hat{\mu}_j)$  is the family-specific variance function.

$$V(\hat{\mu}_j) = \begin{cases} \hat{\mu}_j(1 - \hat{\mu}_j/m_j) & \text{if binomial or Bernoulli } (m_j = 1) \\ \hat{\mu}_j^2 & \text{if gamma} \\ 1 & \text{if Gaussian} \\ \hat{\mu}_j^3 & \text{if inverse Gaussian} \\ \hat{\mu}_j + k\hat{\mu}_j^2 & \text{if negative binomial} \\ \hat{\mu}_j & \text{if Poisson} \end{cases}$$

The response residuals are given by  $r_j^R = y_j - \hat{\mu}_j$ . The working residuals are

$$r_j^W = (y_j - \hat{\mu}_j) \left( \frac{\partial \eta}{\partial \mu} \right)_j$$

and the score residuals are

$$r_j^S = \frac{y_j - \hat{\mu}_j}{V(\hat{\mu}_j)} \left( \frac{\partial \eta}{\partial \mu} \right)_j^{-1}$$

Define  $\widehat{W} = V(\hat{\mu})$  and  $X$  to be the covariate matrix.  $h_j$ , then, is the  $j$ th diagonal of the hat matrix given by

$$\widehat{H} = \widehat{W}^{1/2} X (X^T \widehat{W} X)^{-1} X^T \widehat{W}^{1/2}$$

As a result, the likelihood residuals are given by

$$r_j^L = \text{sign}(y_j - \hat{\mu}_j) \{h_j(r_j^{P'})^2 + (1 - h_j)(r_j^{D'})^2\}^{1/2}$$

where  $r_j^{P'}$  and  $r_j^{D'}$  are the standardized Pearson and standardized deviance residuals, respectively. By *standardized*, we mean that the residual is divided by  $\{1 - h_j\}^{1/2}$ .

Cook's distance is an overall measure of the change in the regression coefficients caused by omitting the  $i$ th observation from the analysis. Computationally, Cook's distance is obtained as

$$C_j = \frac{(r_j^{P'})^2 h_j}{k(1 - h_j)}$$

where  $k$  is the number of regressors, including the constant.

Anscombe residuals are given by

$$r_j^A = \frac{A(y_j) - A(\hat{\mu}_j)}{A'(\hat{\mu}_j)\{V(\hat{\mu}_j)\}^{1/2}}$$

where

$$A(\cdot) = \int \frac{d\mu}{V^{1/3}(\mu)}$$

Deviance residuals may be adjusted (`predict, adjusted`) to make the following correction:

$$r_j^{Da} = r_j^D + \frac{1}{6}\rho_3(\theta)$$

where  $\rho_3(\theta)$  is a family-specific correction. See [Hardin and Hilbe \(2018\)](#) for the exact forms of  $\rho_3(\theta)$  for each family.

## Description

`gmm` performs generalized method of moments (GMM) estimation. With the interactive version of the command, you enter the residual equation for each moment condition directly into the dialog box or on the command line by using substitutable expressions. The moment-evaluator program version gives you greater flexibility in exchange for increased complexity; with this version, you write a program in an ado-file that calculates the moments based on a vector of parameters passed to it.

`gmm` can fit both single- and multiple-equation models. It allows moment conditions of the form  $E\{\mathbf{z}_i u_i(\boldsymbol{\beta})\} = \mathbf{0}$ , where  $\mathbf{z}_i$  is a vector of instruments, and  $u_i(\boldsymbol{\beta})$  is an error term, as well as more general moment conditions of the form  $E\{\mathbf{h}_i(\mathbf{z}_i; \boldsymbol{\beta})\} = \mathbf{0}$ . `gmm` works with cross-sectional, time-series, and longitudinal (panel) data.

## Menu

Statistics > Endogenous covariates > Generalized method of moments estimation

## Syntax

### Interactive version

```
gmm ([reqname1:]rexp1) ([reqname2:]rexp2)...[if] [in] [weight] [, options]
```

### Moment-evaluator program version

```
gmm moment_prog [if] [in] [weight] , { equations(namelist) | nequations(#) }
```

```
{ parameters(namelist) | nparameters(#) } [options] [program_options]
```

*reqname<sub>j</sub>* is the *j*th residual equation name,

*rexp<sub>j</sub>* is the substitutable expression for the *j*th residual equation, and

*moment\_prog* is a moment-evaluator program.

| <i>options</i> | Description |
|----------------|-------------|
|----------------|-------------|

#### Model

```
derivative([reqname|#]/name = dexpjk)
```

specify derivative of *reqname* (or #) with respect to parameter *name*;  
can be specified more than once (interactive version only)

\* twostep

use two-step GMM estimator; the default

\* onestep

use one-step GMM estimator

\* igmm

use iterative GMM estimator

```
variables(varlist)
```

specify variables in model

```
nocommonesample
```

do not restrict estimation sample to be the same for all equations

#### Instruments

```
instruments([reqlist:]varlist [, noconstant])
```

specify instruments; can be specified more than once

```
xtinstruments([reqlist:]varlist , lags(#1/#2))
```

specify panel-style instruments; can be specified more than once

#### Weight matrix

```
wmatrix(wmtype [, independent])
```

specify weight matrix; *wmtype* may be robust, cluster *clustvar*,  
hac *hacspec*, or unadjusted

```
center
```

center moments in weight-matrix computation

```
winitial(iwtype [, independent])
```

specify initial weight matrix; *iwtype* may be unadjusted,  
identify, xt *xtspec*, or the name of a Stata matrix

#### SE/Robust

```
vce(vcetype [, independent])
```

*vcetype* may be robust, cluster *clustvar*, bootstrap,  
jackknife, hac *hacspec*, or unadjusted

```
quickderivatives
```

use alternative method of computing numerical derivatives  
for VCE

## Reporting

|                              |                                                                                                                                                  |
|------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|
| <code>level(#)</code>        | set confidence level; default is <code>level(95)</code>                                                                                          |
| <code>title(string)</code>   | display <i>string</i> as title above the table of parameter estimates                                                                            |
| <code>title2(string)</code>  | display <i>string</i> as subtitle                                                                                                                |
| <code>display_options</code> | control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling |

## Optimization

|                                   |                                                                                                        |
|-----------------------------------|--------------------------------------------------------------------------------------------------------|
| <code>from(initial_values)</code> | specify initial values for parameters                                                                  |
| ‡ <code>igmmiterate(#)</code>     | specify maximum number of iterations for iterated GMM estimator                                        |
| ‡ <code>igmmeps(#)</code>         | specify # for iterated GMM parameter convergence criterion; default is <code>igmmeps(1e-6)</code>      |
| ‡ <code>igmmweps(#)</code>        | specify # for iterated GMM weight-matrix convergence criterion; default is <code>igmmweps(1e-6)</code> |
| <code>optimization_options</code> | control the optimization process; seldom used                                                          |
| <code>coeflegend</code>           | display legend instead of statistics                                                                   |

\*You can specify at most one of these options.

‡These options may be specified only when `igmm` is specified.

| <i>program_options</i> | Description |
|------------------------|-------------|
|------------------------|-------------|

## Model

|                                     |                                                                    |
|-------------------------------------|--------------------------------------------------------------------|
| <code>evaluator_options</code>      | additional options to be passed to the moment-evaluator program    |
| * <code>hasderivatives</code>       | moment-evaluator program can calculate parameter-level derivatives |
| * <code>haslfdderivatives</code>    | moment-evaluator program can calculate linear-form derivatives     |
| † <code>equations(namelist)</code>  | specify residual equation names                                    |
| † <code>nequations(#)</code>        | specify number of residual equations                               |
| ‡ <code>parameters(namelist)</code> | specify parameter names                                            |
| ‡ <code>nparameters(#)</code>       | specify number of parameters                                       |

\*You may not specify both `hasderivatives` and `haslfdderivatives`.

†You must specify `equations(namelist)` or `nequations(#)`; you may specify both.

‡You must specify `parameters(namelist)` or `nparameters(#)`; you may specify both.

$rexp_j$  and  $dexp_{jk}$  may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists.

`bayesboot`, `bootstrap`, `by`, `collect`, `jackknife`, `rolling`, and `statsby` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`aweights` are not allowed with the `jackknife` prefix; see [R] `jackknife`.

`aweights`, `fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

$rexp_j$  and  $dexp_{jk}$  are substitutable expressions, that is, Stata expressions that also contain parameters to be estimated. The parameters are enclosed in curly braces and must satisfy the naming requirements for variables; `{beta}` is an example of a parameter. The notation `{lcname:varlist}` is allowed for linear combinations of multiple covariates and their parameters. For example, `{xb: mpg price turn _cons}` defines a linear combination of the variables `mpg`, `price`, `turn`, and `_cons` (the constant term). See *Substitutable expressions* under *Remarks and examples* below.

## Options

Model

`derivative([reqname|#]/name = dexpjk)` specifies the derivative of residual equation *reqname* or # with respect to parameter *name*. If *reqname* or # is not specified, gmm assumes that the derivative applies to the first residual equation.

For a moment condition of the form  $E\{\mathbf{z}_{ji}u_{ji}(\boldsymbol{\beta})\} = \mathbf{0}$ , `derivative(j/ $\beta_k = dexp_{jk}$ )` is to contain a substitutable expression for  $\partial u_{ji}/\partial \beta_k$ . If you specified *m* as the *reqname*, then for a moment condition of the form  $E\{\mathbf{z}_{mi}u_{mi}(\boldsymbol{\beta})\} = \mathbf{0}$ , you can specify `derivative(m/ $\beta_k = dexp_{mk}$ )`, where *m* is the index of *m*.

*dexp<sub>jk</sub>* uses the same substitutable expression syntax as is used to specify residual equations. If you declare a linear combination in a residual equation, you provide the derivative for the linear combination; gmm then applies the chain rule for you. See [Specifying derivatives](#) under *Remarks and examples* below for examples.

If you do not specify the `derivative()` option, gmm calculates derivatives numerically. You must either specify no derivatives or specify a derivative for each of the *k* parameters that appears in each of the *j* residual equations unless the derivative is identically zero. You cannot specify some analytic derivatives and have gmm compute the rest numerically.

`twostep`, `onestep`, and `igmm` specify which estimator is to be used. You can specify at most one of these options. `twostep` is the default.

`twostep` requests the two-step GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, and then reestimates the parameters based on that weight matrix.

`onestep` requests the one-step GMM estimator. The parameters are estimated based on an initial weight matrix, and no updating of the weight matrix is performed except when calculating the appropriate variance–covariance (VCE) matrix.

`igmm` requests the iterative GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, reestimates the parameters based on that weight matrix, computes a new weight matrix, and so on, to convergence. Convergence is declared when the relative change in the parameter vector is less than `igmmeps()`, the relative change in the weight matrix is less than `igmmweps()`, or `igmmiterate()` iterations have been completed. [Hall \(2005, sec. 2.4 and 3.6\)](#) mentions that there may be gains to finite-sample efficiency from using the iterative estimator.

`variables(varlist)` specifies the variables in the model. gmm ignores observations for which any of these variables has a missing value. If you do not specify `variables()`, then gmm assumes all the observations are valid and issues an error message if any residual equations evaluate to missing for any observations at the initial value of the parameter vector.

`nocommonesample` requests that gmm not restrict the estimation sample to be the same for all equations. By default, gmm will restrict the estimation sample to observations that are available for all equations in the model, mirroring the behavior of other multiple-equation estimators such as `nlsur`, `sureg`, or `reg3`. For certain models, however, different equations can have different numbers of observations. For these models, you should specify `nocommonesample`. See [Dynamic panel-data models](#) below for one application of this option. You cannot specify weights if you specify `nocommonesample`.

## Instruments

`instruments([reqlist:]varlist[, noconstant])` specifies a list of instrumental variables to be used.

If you specify a single residual equation, then you do not need to specify the equations to which the instruments apply; you can omit the *reqlist* and simply specify `instruments(varlist)`. By default, a constant term is included in *varlist*; to omit the constant term, specify `instruments(varlist, noconstant)`.

If your model has multiple moment conditions of the form

$$E \begin{Bmatrix} \mathbf{z}_{1i} u_{1i}(\beta) \\ \dots \\ \mathbf{z}_{qi} u_{qi}(\beta) \end{Bmatrix} = \mathbf{0}$$

then you can specify multiple corresponding residual equations. Then, specify the *reqname* or an *reqlist* to indicate the residual equations for which the list of variables is to be used as instruments if you do not want that list applied to all the residual equations. For example, you might type

```
gmm (main:exp1) (exp2) (exp3), instruments(z1 z2) ///
 instruments(2: z3) instruments(main 3: z4)
```

Variables `z1` and `z2` will be used as instruments for all three equations, `z3` will be used as an instrument for the second equation, and `z4` will be used as an instrument for the first and third equations. Notice that we chose to supply a name for the first residual equation but not the second two, identifying each by its equation number.

*varlist* may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists, respectively.

`xtinstruments([reqlist:]varlist, lags(#1/2))` is for use with panel-data models in which the set of available instruments depends on the time period. As with `instruments()`, you can prefix the list of variables with residual equation names or numbers to target instruments to specific equations. Unlike with `instruments()`, a constant term is not included in *varlist*. You must `xtset` your data before using this option; see [XT] `xtset`.

If you specify

```
gmm ..., xtinstruments(x, lags(1/.)) ...
```

then for panel *i* and period *t*, `gmm` uses  $x_{i,t-1}, x_{i,t-2}, \dots, x_{i1}$  as instruments. More generally, specifying `xtinstruments(x, lags(#1, #2))` uses  $x_{i,t-\#_1}, \dots, x_{i,t-\#_2}$  as instruments; setting `#2 = .` requests all available lags. `#1` and `#2` must be zero or positive integers.

`gmm` automatically excludes observations for which no valid instruments are available. It does, however, include observations for which only a subset of the lags is available. For example, if you request that lags one through three be used, then `gmm` will include the observations for the second and third time periods even though fewer than three lags are available as instruments.

## Weight matrix

`wmatrix(wmtype[, independent])` specifies the type of weight matrix to be used in conjunction with the two-step and iterated GMM estimators.

`wmatrix(robust)`, the default, requests a weight matrix that is appropriate when the errors are independent but not necessarily identically distributed.

`wmatrix(cluster clustvar)` requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by *clustvar*.

`wmatrix(hac hacspec)` requests a heteroskedasticity- and autocorrelation-consistent (HAC) weight matrix. The full syntax of *hacspec* is one of the following:

`wmatrix(hac kernel [#])` requests a HAC weight matrix using the specified kernel (see below) with optional # lags. The bandwidth of a kernel is equal to # + 1. If # is not specified, a kernel with  $N - 2$  lags is used, where  $N$  is the sample size.

`wmatrix(hac kernel opt [#])` requests a HAC weight matrix using the specified kernel (see below), and the lag order is selected using Newey and West's (1994) optimal lag-selection algorithm. # is an optional tuning parameter that affects the lag order selected; see the [discussion](#) in *Methods and formulas*.

*kernel* may be one of the following:

`bartlett` or `nwest` requests the Bartlett (Newey–West) kernel.

`parzen` or `gallant` requests the Parzen (Gallant 1987) kernel.

`quadraticspectral` or `andrews` requests the quadratic spectral (Andrews 1991) kernel.

`wmatrix(unadjusted)` requests a weight matrix that is suitable when the errors are homoskedastic. In some applications, the GMM estimator so constructed is known as the (nonlinear) two-stage least-squares (2SLS) estimator.

`independent` creates a weight matrix that assumes moment conditions are independent. It is often used to replicate other models that can be motivated outside the GMM framework, such as the estimation of a system of equations by system-wide 2SLS. `independent` has no effect if only one residual equation is specified.

`wmatrix()` has no effect if `onestep` is also specified.

`center` requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

`winitial(iwtype[ , independent ])` specifies the weight matrix to use to obtain the first-step parameter estimates.

`winitial(unadjusted)`, the default, requests a weight matrix that assumes the moment conditions are independent and identically distributed. This matrix is of the form  $(\mathbf{Z}'\mathbf{Z})^{-1}$ , where  $\mathbf{Z}$  represents all the instruments specified in the `instruments()` option. To avoid a singular weight matrix, you should specify at least  $q - 1$  moment conditions of the form  $E\{\mathbf{z}_{hi}u_{hi}(\beta)\} = \mathbf{0}$ , where  $q$  is the number of moment conditions, or you should specify `independent`.

`winitial(identity)` requests that the identity matrix be used.

`winitial(xt xtspec)` is for use with dynamic panel-data models in which one of the residual equations is specified in first-differences form. *xtspec* is a string consisting of the letters “L” and “D”, the length of which is equal to the number of residual equations in the model. You specify “L” for a residual equation if that residual equation is written in levels, and you specify “D” for a residual equation if it is written in first differences; *xtspec* is not case sensitive. When you specify this option, you can specify at most one residual equation in levels and one residual equation in first differences. See the examples listed in [Dynamic panel-data models](#) under *Remarks and examples* below.

`winitial(matname)` requests that Stata matrix *matname* be used. You cannot specify `independent` if you specify `winitial(matname)`.

`independent` creates a weight matrix that assumes moment conditions are independent. Elements of the weight matrix corresponding to covariances between two moment conditions are set equal to zero. `independent` has no effect if only one residual equation is specified.

---

#### SE/Robust

`vce(vcetype[, independent])` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` `clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

`vce(unadjusted)` specifies that an unadjusted (nonrobust) VCE matrix be used; this, along with the `twostep` option, results in the “optimal two-step GMM” estimates often discussed in textbooks.

The default `vcetype` is based on the `wmtype` specified in the `wmatrix()` option. If `wmatrix()` is specified but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`.

The syntax for `vcetypes` other than `bootstrap` and `jackknife` is identical to those for `wmatrix()`.

`vce(bootstrap)` or `vce(jackknife)` results in standard errors based on the bootstrap or jackknife, respectively. See [R] [vce\\_option](#), [R] [bootstrap](#), and [R] [jackknife](#) for more information on these VCEs.

`quickderivatives` requests that an alternative method be used to compute the numerical derivatives for the VCE. This option has no effect if you specify the `derivatives()`, `hasderivatives`, or `haslfdderivatives` option.

The VCE depends on a matrix of partial derivatives that `gmm` must compute numerically unless you supply analytic derivatives. This Jacobian matrix will be especially large if your model has many instruments, residual equations, or parameters.

By default, `gmm` computes each element of the Jacobian matrix individually, searching for an optimal step size each time. Although this procedure results in accurate derivatives, it is computationally taxing: `gmm` may have to evaluate the moments of your model five or more times for each element of the Jacobian matrix.

When you specify the `quickderivatives` option, `gmm` computes all derivatives corresponding to a parameter at once, using a fixed step size proportional to the parameter’s value. This method requires just two evaluations of the model’s moments to compute an entire column of the Jacobian matrix and therefore has the most impact when you specify many instruments or residual equations.

Most of the time, the two methods produce virtually identical results, but the `quickderivatives` method may fail if a residual equation is highly nonlinear or if instruments differ by orders of magnitude. In the rare case where you specify `quickderivatives` and obtain suspiciously large or small standard errors, try refitting your model without this option.

---

#### Reporting

`level(#)`; see [R] [Estimation options](#).

`title(string)` specifies an optional title that will be displayed just above the table of parameter estimates.

`title2(string)` specifies an optional subtitle that will be displayed between the title specified in `title()` and the table of parameter estimates. If `title2()` is specified but `title()` is not, `title2()` has the same effect as `title()`.

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

#### Optimization

`from(initial_values)` specifies the initial values to begin the estimation. You can specify a parameter name, its initial value, another parameter name, its initial value, and so on, or you can specify a  $1 \times k$  matrix, where  $k$  is the number of parameters in the model. For example, to initialize `alpha` to 1.23 and `delta` to 4.57, you would type

```
gmm ..., from(alpha 1.23 delta 4.57) ...
```

or equivalently

```
matrix define initval = (1.23, 4.57)
gmm ..., from(initval) ...
```

Initial values declared in the `from()` option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, `gmm` exits with an error message. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model.

`igmmiterate(#)`, `igmmeps(#)`, and `igmmweps(#)` control the iterative process for the iterative GMM estimator. These options can be specified only if you also specify `igmm`.

`igmmiterate(#)` specifies the maximum number of iterations to perform with the iterative GMM estimator. The default is the number set using `set maxiter`, which is 300 by default.

`igmmeps(#)` specifies the convergence criterion used for successive parameter estimates when the iterative GMM estimator is used. The default is `igmmeps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `igmmeps()` and the relative difference between successive estimates of the weight matrix is less than `igmmweps()`.

`igmmweps(#)` specifies the convergence criterion used for successive estimates of the weight matrix when the iterative GMM estimator is used. The default is `igmmweps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `igmmeps()` and the relative difference between successive estimates of the weight matrix is less than `igmmweps()`.

*optimization\_options*: `technique()`, `conv_maxiter()`, `conv_ptol()`, `conv_vtol()`, `conv_nrtol()`, `tracelevel()`. `technique()` specifies the optimization technique to use; `gn` (the default), `nr`, `dfp`, and `bfgs` are allowed. `conv_maxiter()` specifies the maximum number of iterations; `conv_ptol()`, `conv_vtol()`, and `conv_nrtol()` specify the convergence criteria for the parameters, gradient, and scaled Hessian, respectively. `tracelevel()` allows you to obtain additional details during the iterative process. See [M-5] [optimize\(\)](#).

The following options pertain only to the moment-evaluator program version of `gmm`.

Model

`evaluator_options` refer to any options allowed by your `moment_prog`.

`hasderivatives` and `haslfdderivatives` indicate that you have written your moment-evaluator program to compute derivatives. You may specify one or the other but not both. If you do not specify either of these options, `gmm` computes the derivatives numerically.

`hasderivatives` indicates that your moment-evaluator program computes parameter-level derivatives.

`haslfdderivatives` indicates that your moment-evaluator program computes equation-level derivatives and is useful only when you specify the parameters of your model using the `{lcname:varlist}` syntax of the `parameters()` option.

See *Details of moment-evaluator programs* below for more information.

`equations(namelist)` specifies the names of the residual equations in the model. If you specify both `equations()` and `nequations()`, the number of names in the former must match the number specified in the latter.

`nequations(#)` specifies the number of residual equations in the model. If you do not specify names with the `equations()` option, `gmm` numbers the residual equations 1, 2, 3, .... If you specify both `equations()` and `nequations()`, the number of names in the former must match the number specified in the latter.

`parameters(namelist)` specifies the names of the parameters in the model. The names of the parameters must comply with the naming conventions of Stata's variables; see [U] 11.3 **Naming conventions**.

Alternatively, you can use parameter equation notation to specify linear combinations of parameters. Each linear combination is of the form `{lcname:varlist}`, where `varlist` is one or more variable names. Specify the **system variable** `_cons` in `varlist` to include a constant term. Distinguish between `{lcname:varlist}`, in which `lcname` identifies the linear combination, and `(reqname:rexp)`, in which `reqname` identifies the residual equation. When you use linear-combination syntax, `gmm` prepends each element of the parameter vector passed to your evaluator program with `lcname:` to generate unique names.

If you specify both `parameters()` and `nparameters()`, the number of names in the former must match the number specified in the latter.

`nparameters(#)` specifies the number of parameters in the model. If you do not specify names with the `parameters()` option, `gmm` names them `b1`, `b2`, ..., `b#`. If you specify both `parameters()` and `nparameters()`, the number of names in the former must match the number specified in the latter.

The following option is available with `gmm` but is not shown in the dialog box:

`coeflegend`; see [R] **Estimation options**.

## Introduction

The GMM estimator is a workhorse of modern econometrics and is discussed in all the leading textbooks, including Cameron and Trivedi (2005, 2022), Davidson and MacKinnon (1993), Greene (2018, 500–534), Ruud (2000), Hayashi (2000), Wooldridge (2010), Hamilton (1994), and Baum (2006). An excellent treatise on GMM with a focus on time-series applications is Hall (2005). The collection of papers by Mátyás (1999) provides both theoretical and applied aspects of GMM. Here we give a brief introduction to the methodology and emphasize how the various options of `gmm` are used.

The starting point for the GMM estimator is the analogy principle, which says we can estimate a parameter by replacing a population moment condition with its sample analogue. For example, the mean of an independent and identically distributed (i.i.d.) population is defined as the value  $\mu$  such that the first (central) population moment is zero; that is,  $\mu$  solves  $E(y - \mu) = 0$ , where  $y$  is a random draw from the population. The analogy principle tells us that to obtain an estimate,  $\hat{\mu}$ , of  $\mu$ , we replace the population-expectations operator with its sample analogue (Manski 1988; Wooldridge 2010),

$$E(y - \mu) = 0 \longrightarrow \frac{1}{N} \sum_{i=1}^N (y_i - \hat{\mu}) = 0 \longrightarrow \hat{\mu} = \frac{1}{N} \sum_{i=1}^N y_i$$

where  $N$  denotes sample size, and  $y_i$  represents the  $i$ th observation of  $y$  in our dataset. The estimator  $\hat{\mu}$  is known as the method of moments (MM) estimator because we started with a population moment condition and then applied the analogy principle to obtain an estimator that depends on the observed data.

Ordinary least-squares (OLS) regression can also be viewed as an MM estimator. In the model

$$y = \mathbf{x}'\boldsymbol{\beta} + u$$

we assume that  $u$  has mean zero conditional on  $\mathbf{x}$ :  $E(u|\mathbf{x}) = 0$ . This conditional expectation implies the unconditional expectation  $E(\mathbf{x}u) = \mathbf{0}$  because, with the law of iterated expectations,

$$E(\mathbf{x}u) = E_{\mathbf{x}} \{E(\mathbf{x}u|\mathbf{x})\} = E_{\mathbf{x}} \{\mathbf{x} E(u|\mathbf{x})\} = \mathbf{0}$$

(Using the law of iterated expectations to derive unconditional expectations based on conditional expectations, perhaps motivated by subject theory, is extremely common in GMM estimation.) Continuing, we see that

$$E(\mathbf{x}u) = E\{\mathbf{x}(y - \mathbf{x}'\boldsymbol{\beta})\} = \mathbf{0}$$

Applying the analogy principle, we obtain

$$E\{\mathbf{x}(y - \mathbf{x}'\boldsymbol{\beta})\} \rightarrow \frac{1}{N} \sum_{i=1}^N \mathbf{x}_i(y_i - \mathbf{x}'_i\boldsymbol{\beta}) = \mathbf{0}$$

so that

$$\widehat{\boldsymbol{\beta}} = \left( \sum_i \mathbf{x}_i \mathbf{x}'_i \right)^{-1} \sum_i \mathbf{x}_i y_i$$

which is just the more familiar formula  $\widehat{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1} \mathbf{X}'\mathbf{y}$  written with summation notation.

In both of the previous examples, the number of parameters we were estimating equaled the number of moment conditions. In the first example, we estimated one parameter,  $\mu$ , and had one moment condition  $E(y - \mu) = 0$ . In the second example, the parameter vector  $\boldsymbol{\beta}$  had  $k$  elements, as did the vector of regressors  $\mathbf{x}$ , yielding  $k$  moment conditions. Ignoring peculiar cases, we see that a model of  $m$  equations in  $m$  unknowns has a unique solution; and because the residual equations in these examples were linear, we could solve for the parameters analytically. If the moment conditions had been nonlinear, we would have had to use numerical techniques to solve for the parameters, but that is not a significant limitation with modern computers.

What if we have more moment conditions than parameters? Say we have  $q$  moment conditions and  $k$  parameters. A model of  $q > k$  equations in  $k$  unknowns does not have a unique solution. Any size- $k$  subset of the moment conditions would yield a consistent parameter estimate, though the parameter estimate would in general be different depending on which  $k$  moment conditions we used.

For concreteness, let's return to our regression model,

$$y = \mathbf{x}'\boldsymbol{\beta} + u$$

Now, however, we no longer wish to assume that  $E(\mathbf{x}u) = \mathbf{0}$ ; we suspect that the error term  $u$  affects one or more elements of  $\mathbf{x}$ . Thus, we can no longer use the OLS estimator. Suppose we have a vector  $\mathbf{z}$  with the properties that  $E(\mathbf{z}u) = \mathbf{0}$ , that the rank of  $E(\mathbf{z}'\mathbf{z})$  equals  $q$ , and that the rank of  $E(\mathbf{z}'\mathbf{x}) = k$ . The first assumption simply states that  $\mathbf{z}$  is not correlated with the error term. The second assumption rules out perfect collinearity among the elements of  $\mathbf{z}$ . The third assumption, known as the rank condition in econometrics, ensures that  $\mathbf{z}$  is sufficiently correlated with  $\mathbf{x}$  and that the estimator is feasible. If some elements of  $\mathbf{x}$  are not correlated with  $u$ , then they should also appear in  $\mathbf{z}$ .

If  $q < k$ , then the rank of  $E(\mathbf{z}'\mathbf{x}) < k$ , which violates the rank condition.

If  $q = k$ , then we can use the simpler MM estimator we already discussed; we would obtain what is sometimes called the simple instrumental-variables estimator  $\widehat{\boldsymbol{\beta}} = \left( \sum_i \mathbf{z}_i \mathbf{z}'_i \right)^{-1} \sum_i \mathbf{z}_i y_i$ . The rank condition ensures that  $\sum_i \mathbf{z}_i \mathbf{z}'_i$  is invertible, at least in the population.

If  $q > k$ , the GMM estimator chooses the value,  $\widehat{\boldsymbol{\beta}}$ , that minimizes a quadratic function of the moment conditions. We could define

$$\widehat{\boldsymbol{\beta}} \equiv \arg \min_{\boldsymbol{\beta}} \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\boldsymbol{\beta}) \right\}' \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\boldsymbol{\beta}) \right\}$$

where for our linear regression example  $u_i(\boldsymbol{\beta}) = y_i - \mathbf{x}'_i\boldsymbol{\beta}$ . This estimator tries to make the moment conditions as close to zero as possible. This simple estimator, however, applies equal weight to each of the moment conditions; and as we will see later, we can obtain more efficient estimators by choosing to weight some moment conditions more highly than others.

Consider the quadratic function

$$Q(\beta) = \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\beta) \right\}' \mathbf{W} \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\beta) \right\}$$

where  $\mathbf{W}$  is a symmetric positive-definite matrix known as a weight matrix. Then we define the GMM estimator as

$$\widehat{\beta} \equiv \arg \min_{\beta} Q(\beta) \quad (1)$$

Continuing with our regression model example, if we choose

$$\mathbf{W} = \left( \frac{1}{N} \sum_i \mathbf{z}_i \mathbf{z}_i' \right)^{-1}$$

then we obtain

$$\widehat{\beta} = \left\{ \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{z}_i' \right) \left( \frac{1}{N} \sum_i \mathbf{z}_i \mathbf{z}_i' \right)^{-1} \left( \frac{1}{N} \sum_i \mathbf{z}_i \mathbf{x}_i' \right) \right\}^{-1} \times \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{z}_i' \right) \left( \frac{1}{N} \sum_i \mathbf{z}_i \mathbf{z}_i' \right)^{-1} \left( \frac{1}{N} \sum_i \mathbf{z}_i y_i \right)$$

which is the well-known two-stage least-squares (2SLS) estimator. Our choice of weight matrix here was based on the assumption that  $u$  was homoskedastic. A feature of GMM estimation is that by selecting different weight matrices, we can obtain estimators that can tolerate heteroskedasticity, clustering, autocorrelation, and other features of  $u$ . See [R] [ivregress](#) for more information about the 2SLS and linear GMM estimators.

Returning to the case where the model is “just identified”, meaning that  $q = k$ , if we apply the GMM estimator, we will obtain the same estimate,  $\widehat{\beta}$ , regardless of our choice of  $\mathbf{W}$ . Because  $q = k$ , if a unique solution exists, it will set all the sample moment conditions jointly to zero, so  $\mathbf{W}$  has no impact on the value of  $\beta$  that minimizes the objective function.

We will highlight other features of the GMM estimator and the `gmm` command as we proceed through examples. First, though, we discuss how to specify moment conditions by using substitutable expressions.

## Substitutable expressions

To use the interactive version of `gmm`, you define the moment conditions by using substitutable expressions. Your moment conditions are of the form  $E\{z_i' u_i(\beta)\} = \mathbf{0}$ , where  $u_i(\beta)$  is a residual expression that depends on the parameter vector  $\beta$  as well as variables in your dataset, though we suppress expressing the variables for notational simplicity.

`gmm` requires you to write a substitutable expression for  $u_i(\beta)$ . This substitutable expression is the right-hand side of the model written in terms of  $u$ , or in the language of Stata syntax, a “residual equation”. For example, suppose you want to fit the function  $y = f(\mathbf{x}; \beta) + u$ . In this example,  $u_i(\beta) = u = y - f(\mathbf{x}; \beta)$ , so you would type

```
gmm (y - expression for f(x; beta)), ...
```

Note that we are not restricted to models with additive error terms.

In general, there are three rules to follow when defining substitutable expressions:

1. Parameters of the model are bound in curly braces: `{b0}`, `{param}`, etc. Parameter names must follow the same conventions as variable names. See [U] 11.3 [Naming conventions](#).
2. Initial values for parameters are given by including an equal sign and the initial value inside the curly braces: `{b0=1}`, `{param=3.571}`, etc.

You can also specify initial values by using the `from()` option. Initial values specified in `from()` override whatever initial values are given within the substitutable expression. If you do not specify an initial value for a parameter, it is initialized to 0.

3. Linear combinations of variables can be included using the notation `{lcname:varlist}`: `{xb: mpg price weight}`, `{score: w x z}`, etc. Parameters of linear combinations are initialized to 0.

Substitutable expressions may use any mathematical expression involving scalars and variables. See [U] 13.2 [Operators](#) and [U] 13.3 [Functions](#) for more information on expressions.

The notation `{xb: x1 x2 x3}` tells `gmm` that you want a linear combination of the variables `x1`, `x2`, and `x3`. We named this linear combination `xb`, so `gmm` will name the three parameters `xb:x1`, `xb:x2`, and `xb:x3`, which corresponds to the three variables `x1`, `x2`, and `x3` in the `xb` equation. Specify `_cons` to include a constant term in a linear combination. Factor variables and time-series operators are allowed; see [U] 11.4.3 [Factor variables](#) and [U] 11.4.4 [Time-series varlists](#).

Once we have declared the variables in the linear combination `xb`, we can refer to the linear combination in our substitutable expression by using the notation `xb:.` The colon is not optional; it tells `gmm` that you are referring to a previously declared linear combination, not an individual parameter. This shorthand notation is also handy when specifying derivatives, as we will show later.

## ▷ Example 1: OLS regression

In [Introduction](#), we stated that OLS is an MM estimator. Say that we want to fit the model

$$\text{mpg} = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{length} + u$$

where  $u$  is an i.i.d. error term. Recall that the moment condition for OLS regression is  $E(\mathbf{x}u) = \mathbf{0}$ , where  $\mathbf{x}$ , the list of instruments, is the same as the list of regressors in the model. Writing this in the form required for a `gmm` substitutable expression, we have

$$u = \text{mpg} - \beta_0 - \beta_1 \text{weight} - \beta_2 \text{length}$$

The right-hand side of the equation is the substitutable expression that we will provide to `gmm`. We give  $\beta_0$ ,  $\beta_1$ , and  $\beta_2$  the parameter names `b0`, `b1`, and `b2` and enclose them in curly braces. Because linear combinations declared in substitutable expressions do not include a constant term by default, we include our own (`b0`). We specify the regressors, `weight` and `length`, with their respective parameters and also in the `instruments()` option. `gmm` includes a constant term in the instrument list by default, so we do not need to add an additional term there. Thus, our command is

```

. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. gmm (mpg - {b1}*weight - {b2}*length - {b0}), instruments(weight length)
Step 1:
Iteration 0: GMM criterion Q(b) = 475.4138
Iteration 1: GMM criterion Q(b) = 2.696e-20
Iteration 2: GMM criterion Q(b) = 3.329e-27
Step 2:
Iteration 0: GMM criterion Q(b) = 5.109e-28
Iteration 1: GMM criterion Q(b) = 7.237e-32
note: model is exactly identified.
GMM estimation
Number of parameters = 3
Number of moments = 3
Initial weight matrix: Unadjusted Number of obs = 74
GMM weight matrix: Robust

```

|     | Robust      |           |       |       |                      |           |
|-----|-------------|-----------|-------|-------|----------------------|-----------|
|     | Coefficient | std. err. | z     | P> z  | [95% conf. interval] |           |
| /b1 | -.0038515   | .0019472  | -1.98 | 0.048 | -.0076678            | -.0000351 |
| /b2 | -.0795935   | .0677528  | -1.17 | 0.240 | -.2123866            | .0531996  |
| /b0 | 47.88487    | 7.50599   | 6.38  | 0.000 | 33.1734              | 62.59634  |

```
Instruments for equation 1: weight length _cons
```

Because the number of moments equals the number of parameters we are estimating, the model is said to be “just identified” or “exactly identified”. Therefore, the choice of weight matrix has no impact on the solution to (1), and the criterion function  $Q(\beta)$  achieves its minimum value at 0.

The OLS estimator is a one-step GMM estimator, but we did not bother to specify the `onestep` option, because the model is just identified. Doing a second step of GMM estimation affects neither the point estimates nor the standard errors, so to keep the syntax as simple as possible, we did not include the `onestep` option. The first step of estimation resulted in  $Q(\beta) = 0$  as expected, and the second step of estimation did not change the minimized value of  $Q(\beta)$ . (The final iterations of the first and second steps result in  $Q(\beta)$  values of 0 for all practical purposes.)

When you do not specify either the `wmatrix()` or the `vce()` option, `gmm` reports heteroskedasticity-robust standard errors. The parameter estimates reported here match those that we would obtain from the command

```
. regress mpg weight length, vce(robust)
```

The standard errors reported by that `regress` command would be larger than those reported by `gmm` by a factor of  $\sqrt{74/71}$  because `regress` makes a small-sample adjustment to the estimated variance matrix while `gmm` does not. Likewise, if we had specified the `vce(unadjusted)` option with our `gmm` command, then our standard errors would differ by a factor of  $\sqrt{74/71}$  from those reported by `regress` without the `vce(robust)` option.

We could have submitted our substitutable expression using the notation for linear combinations of parameters. If we select `xb` as the name of our parameter equation, we could type

```
. gmm (mpg - {xb: weight length _cons}), instruments(weight length)
```

Note how we specified the `instruments()` option. In *Introduction*, we mentioned that the moment conditions for the 2SLS estimator are  $E(\mathbf{z}u) = \mathbf{0}$ , and we mentioned that if some elements of  $\mathbf{x}$  (the regressors) are not endogenous, then they should also appear in  $\mathbf{z}$ . In this model, we assume the regressor `pcurban` is exogenous, so we included it in the list of instrumental variables. Commands like `ivregress`, `ivprobit`, and `ivtobit` accept standard *varlists*, so they can deduce the exogenous regressors in the model. Because `gmm` accepts arbitrary functions in the form of substitutable expressions, it has no way of discerning the exogenous variables of the model on its own.

Also notice that we specified the `onestep` option. The 2SLS estimator is a one-step GMM estimator that is based on a weight matrix that assumes the error terms are i.i.d. Unlike the previous example, this example had more instruments than parameters, so the minimized value of  $Q(\beta)$  is nonzero. We discuss the weight matrix and its relationship to two-step estimation next.

◀

## The weight matrix and two-step estimation

Recall our definition of the GMM estimator given in (1). The estimator,  $\widehat{\beta}$ , depends on the choice of the weight matrix,  $\mathbf{W}$ . Under relatively mild assumptions, our estimator,  $\widehat{\beta}$ , is consistent regardless of the choice of  $\mathbf{W}$ , so how are we to decide what  $\mathbf{W}$  to use? The most common solution is to use the two-step estimator, which we now describe.

A key result in Hansen's (1982) seminal paper is that if we denote by  $\mathbf{S}$  the covariance matrix of the moment conditions, then the optimal (in a way we make precise later) GMM estimator is the one that uses a weight matrix equal to the inverse of the moment covariance matrix. That is, if we let  $\mathbf{S} = \text{Cov}(\mathbf{z}u)$ , then we want to use  $\mathbf{W} = \mathbf{S}^{-1}$ . But how do we obtain  $\mathbf{S}$  in the first place?

If we assume that the errors are i.i.d., then

$$\text{Cov}(\mathbf{z}u) = E(u^2 \mathbf{z}\mathbf{z}') = \sigma^2 E(\mathbf{z}\mathbf{z}')$$

where  $\sigma^2$  is the variance of  $u$ . Because  $\sigma^2$  is a positive scalar, we can ignore it when solving (1). Thus, we compute

$$\widehat{\mathbf{W}}_1 = \left( \frac{1}{N} \sum_i \mathbf{z}_i \mathbf{z}_i' \right)^{-1} \quad (2)$$

which does not depend on any unknown model parameters. (Notice that  $\widehat{\mathbf{W}}_1$  is the same weight matrix used in 2SLS.) Given  $\widehat{\mathbf{W}}_1$ , we can solve (1) to obtain an initial estimate, say,  $\widehat{\beta}_1$ .

Our estimate,  $\widehat{\beta}_1$ , is consistent, so by Slutsky's theorem, the sample residuals  $\widehat{u}$  computed at this value of  $\beta$  will also be consistent. Using virtually the same arguments used to justify the Huber/Eicker/White heteroskedasticity-robust VCE, if we assume that the residuals are independent though not identically distributed, we can estimate  $\mathbf{S}$  as

$$\widehat{\mathbf{S}} = \frac{1}{N} \sum_i \widehat{u}_i^2 \mathbf{z}_i \mathbf{z}_i'$$

Then, in the second step, we re-solve (1), using  $\widehat{\mathbf{W}}_2 = \widehat{\mathbf{S}}^{-1}$ , which yields the two-step GMM estimate  $\widehat{\beta}_2$ . If the residuals exhibit clustering, you can specify `wmatrix(cluster varname)` so that `gmm` computes a weight matrix that does not assume the  $u_i$ 's are independent within clusters identified by *varname*. You can specify `wmatrix(hac ...)` to obtain weight matrices that are suitable for when the  $u_i$ 's exhibit autocorrelation as well as heteroskedasticity.

We could take the point estimates from the second round of estimation and use them to compute yet another weight matrix,  $\widehat{\mathbf{W}}_3$ , say, re-solve (1) yet again, and so on, stopping when the parameters or weight matrix do not change much from one iteration to the next. This procedure is known as the iterative GMM estimator and is obtained with the `igmm` option. Asymptotically, the two-step and iterative GMM estimators have the same distribution. However, Hall (2005, 90) suggests that the iterative estimator may have better finite-sample properties.

Instead of computing  $\widehat{\mathbf{W}}_1$  as in (2), we could simply choose  $\widehat{\mathbf{W}}_1 = \mathbf{I}$ , the identity matrix. The initial estimate,  $\widehat{\beta}_1$ , would still be consistent. You can request this behavior by specifying the `winitial(identity)` option. However, if you specify all of your moment conditions of the form  $E(\mathbf{z}u) = \mathbf{0}$ , we recommend using the default `winitial(unadjusted)` instead; the rescaling of the moment conditions implied by using a homoskedastic initial weight matrix makes the numerical routines used to solve (1) more stable.

If you fit a model with more than one of the moment conditions of the form  $E\{h(\mathbf{z}; \beta)\} = \mathbf{0}$ , then you must use `winitial(identity)` or `winitial(unadjusted, independent)`. With moment conditions of that form, you do not specify a list of instruments, and `gmm` cannot evaluate (2)—the matrix expression in parentheses would necessarily be singular, so it cannot be inverted.

### ▷ Example 3: Two-step linear GMM estimator

From the previous discussion and the comments in [Introduction](#), we see that the linear 2SLS estimator is a one-step GMM estimator where we use the weight matrix defined in (2) that assumes the errors are i.i.d. If we use the 2SLS estimate of  $\beta$  to obtain the sample residuals, compute a new weight matrix based on those residuals, and then do a second step of GMM estimation, we obtain the linear two-step GMM estimator as implemented by `ivregress gmm`.

In [example 3](#) of [\[R\] ivregress](#), we fit the model of rental rates as discussed in [example 2](#) above. We now allow the residuals to be heteroskedastic, though we will maintain our assumption that they are independent. We type

```
. gmm (rent - {xb:hsngval pcturban _cons}), instruments(pcturban faminc reg2-reg4)

Instruments for equation 1: pcturban faminc reg2 reg3 reg4 \_cons

By default, `gmm` computes a heteroskedasticity-robust weight matrix before the second step of estimation, though we could have specified `wmatrix(robust)` if we wanted to be explicit. Because we did not specify the `vce()` option, `gmm` used a heteroskedasticity-robust one. Our results match those in [example 3](#) of [R] `ivregress`. Moreover, the only substantive difference between this example and [example 2](#) is that here we did not specify the `onestep` option, so we obtain the two-step estimates. ◀

## Obtaining standard errors

This section is a bit more theoretical and can be skipped on first reading. However, the information is sufficiently important that you should return to this section at some point.

So far in our discussion, we have focused on point estimation without much mention of how we obtain the standard errors of the estimates. We also mentioned that if we choose  $\mathbf{W}$  to be the inverse of the covariance matrix of the moment conditions, then we obtain the “optimal” GMM estimator. We elaborate those points now.

Using mostly standard statistical arguments, we can show that for the GMM estimator defined in (1), the variance of  $\hat{\beta}$  is given by

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \{ \overline{\mathbf{G}}(\hat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\hat{\beta}) \}^{-1} \overline{\mathbf{G}}(\hat{\beta})' \mathbf{W} \mathbf{S} \overline{\mathbf{G}}(\hat{\beta}) \{ \overline{\mathbf{G}}(\hat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\hat{\beta}) \}^{-1} \quad (3)$$

where

$$\overline{\mathbf{G}}(\hat{\beta}) = \frac{1}{N} \sum_i \mathbf{z}_i \left. \frac{\partial u_i}{\partial \beta} \right|_{\beta=\hat{\beta}} \quad \text{or} \quad \overline{\mathbf{G}}(\hat{\beta}) = \frac{1}{N} \sum_i \left. \frac{\partial \mathbf{h}_i}{\partial \beta} \right|_{\beta=\hat{\beta}}$$

as the case may be and  $\mathbf{S} = E(\mathbf{z}u u' \mathbf{z}')$ .

Assuming the `vce(unadjusted)` option is not specified, `gmm` reports standard errors based on the robust variance matrix defined in (3). For the two-step estimator,  $\mathbf{W}$  is the weight matrix requested with the `wmatrix()` option, and it is calculated based on the residuals obtained after the first estimation step. The second-step point estimates and residuals are obtained, and  $\mathbf{S}$  is calculated based on the specification of the `vce()` option. For the iterated estimator,  $\mathbf{W}$  is calculated based on the second-to-last round of estimation, while  $\mathbf{S}$  is based on the residuals obtained after the last round of estimation. Computation of the covariance matrix for the one-step estimator is, perhaps surprisingly, more involved; we discuss the covariance matrix with the one-step estimator in the technical note at the end of this section.

If the model is exactly identified, the matrix  $\overline{\mathbf{G}}(\hat{\beta})$  is square, and (3) simplifies to the following:

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \overline{\mathbf{G}}(\hat{\beta})^{-1} \mathbf{S} (\overline{\mathbf{G}}(\hat{\beta}))^{-1}$$

If we choose the weight matrix to be the inverse of the covariance matrix of the moment conditions so that  $\mathbf{W} = \mathbf{S}^{-1}$ , then (3) simplifies substantially:

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \{ \overline{\mathbf{G}}(\hat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\hat{\beta}) \}^{-1} \quad (4)$$

The GMM estimator constructed using this choice of weight matrix along with the covariance matrix in (4) is known as the “optimal” GMM estimator. One can show that if in fact  $\mathbf{W} = \mathbf{S}^{-1}$ , then the variance in (4) is smaller than the variance in (3) of any other GMM estimator based on the same moment conditions but with a different choice of weight matrix. Thus, the optimal GMM estimator is also known as the efficient GMM estimator because it has the smallest variance of any estimator based on the given moment conditions.

To obtain standard errors from `gmm` based on the optimal GMM estimator, you specify the `vce(unadjusted)` option. We call that VCE unadjusted because we do not recompute the residuals after estimation to obtain the matrix  $\mathbf{S}$  required in (3) or allow for the fact that those residuals may not be i.i.d. Some statistical packages by default report standard errors based on (4) and offer standard errors based on (3) only as an option or not at all. While the optimal GMM estimator is theoretically appealing, Cameron and Trivedi (2005, 177) suggest that in finite samples, it need not perform better than the GMM estimator that uses (3) to obtain standard errors.

#### □ Technical note

Computing the covariance matrix of the parameters after using the one-step estimator is actually a bit more complex than after using the two-step or iterative estimator. We can illustrate most of the intricacies by using linear regression with moment conditions of the form  $E\{\mathbf{x}(y - \mathbf{x}'\boldsymbol{\beta})\} = \mathbf{0}$ .

If you specify `winitial(unadjusted)` and `vce(unadjusted)`, then the initial weight matrix will be computed as

$$\widehat{\mathbf{W}}_1 = \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{x}'_i \right)^{-1} \quad (5)$$

Moreover, for linear regression, we can show that

$$\overline{\mathbf{G}}(\widehat{\boldsymbol{\beta}}) = \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{x}'_i$$

so that (4) becomes

$$\begin{aligned} \text{Var}(\widehat{\boldsymbol{\beta}}) &= \frac{1}{N} \left\{ \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{x}'_i \right) \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{x}'_i \right)^{-1} \left( \frac{1}{N} \sum_i \mathbf{x}_i \mathbf{x}'_i \right) \right\}^{-1} \\ &= \left( \sum_i \mathbf{x}_i \mathbf{x}'_i \right)^{-1} \\ &= (\mathbf{X}'\mathbf{X})^{-1} \end{aligned} \quad (6)$$

However, we know that the nonrobust covariance matrix for the OLS estimator is actually  $\widehat{\sigma}^2(\mathbf{X}'\mathbf{X})^{-1}$ . What is missing from (6) is the scalar  $\widehat{\sigma}^2$ , the estimated variance of the residuals. When you use the one-step estimator and specify `winitial(unadjusted)`, the weight matrix (5) does not include the  $\widehat{\sigma}^2$  term because `gmm` does not have a consistent estimate of  $\boldsymbol{\beta}$  from which it can then estimate  $\sigma^2$ . The point estimates are still correct because multiplying the weight matrix by a scalar factor does not affect the solution to the minimization problem.

To circumvent this issue, if you specify `winitial(unadjusted)` and `vce(unadjusted)`, `gmm` uses the estimated  $\widehat{\boldsymbol{\beta}}$  (which is consistent) to obtain a new unadjusted weight matrix that does include the term  $\widehat{\sigma}^2$  so that evaluating (4) will yield correct standard errors.

If you use the two-step or iterated GMM estimator, this extra effort is not needed to obtain standard errors because the first-step (and subsequent steps') estimate of  $\boldsymbol{\beta}$  is consistent and can be used to estimate  $\sigma^2$  or some other weight matrix based on the `wmatrix()` option. Straightforward algebra shows that this extra effort is also not needed if you request any type of adjusted (robust) covariance matrix with the one-step estimator.

A similar issue arises when you specify `winitial(identity)` and `vce(unadjusted)` with the one-step estimator. Again the solution is to compute an unadjusted weight matrix after obtaining  $\widehat{\beta}$  so that (4) provides the correct standard errors.

We have illustrated the problem and solution using a single-equation linear model. However, the problem arises whenever you use the one-step estimator with an unadjusted VCE, regardless of the number of equations, and `gmm` handles all the details automatically. Computation of Hansen's  $J$  statistic presents an identical issue, and `gmm` takes care of that as well.

If you supply your own initial weight matrix by using `winitial(matname)`, then the standard errors (as well as the  $J$  statistic reported by `estat overid`) are based on that weight matrix. You should verify that the weight matrix you provide will yield appropriate statistics. □

## Factor-variable coefficients in multiple residual functions

The long example in this section uses `gmm` to replicate the results produced by `regress` with factor variables and `margins`. It illustrates how to refer to the coefficients on factor variables in linear combinations in subsequent residual functions. The example also shows how to use `gmm` to address the two-step estimation problem, or the inconsistency of standard errors produced by two-step estimators that depend on previously estimated parameters.

### ► Example 4: Means of linear combinations of factor variables

The mean of a variable when everyone in a population receives a given treatment level is known as a potential-outcome mean. We use `regress` and `margins` to estimate the potential-outcome means of a mother's smoking behavior while pregnant on the birthweight of her baby after controlling for the mother's age and an indicator for whether the mother had a prenatal visit in the first trimester. We use an extract of data from Cattaneo (2010) in which `bweight` is the baby's birthweight in grams, `mbsmoke` is a binary variable indicating whether a mother smoked while pregnant, `mage` is the mother's age, and `prenatal1` is a binary variable indicating whether the mother had a prenatal visit in the first trimester.

We use regress to estimate the regression coefficients.

We used factor variables to interact mbsmoke with the other covariates to allow for separate coefficients for smoking and nonsmoking mothers.

The postestimation command margins uses the estimated regression coefficients to estimate the potential-outcome means of bweight, first assuming that no mother smoked and then assuming that all mothers smoked.

```
. margins i.mbsmoke, vce(unconditional)
Predictive margins
```

Number of obs = 4,642

Expression: Linear prediction, predict()

| mbsmoke   | Unconditional |           |        |       |                      |          |
|-----------|---------------|-----------|--------|-------|----------------------|----------|
|           | Margin        | std. err. | t      | P> t  | [95% conf. interval] |          |
| Nonsmoker | 3407.506      | 9.346894  | 364.56 | 0.000 | 3389.181             | 3425.83  |
| Smoker    | 3138.23       | 21.20463  | 148.00 | 0.000 | 3096.659             | 3179.801 |

Note that the standard errors for the estimated means account for the estimation error in the estimated coefficients used to compute them.

Before using `gmm` to simultaneously estimate the regression coefficients and the potential-outcome means, we demonstrate the equivalence of point estimates from `gmm` and `regress` and illustrate the two-step estimation problem. First, we use `gmm` to estimate just the regression coefficients. Note that we specify the factor variables in the linear combination `xb`: and in the instrument list.

```

```

We specified the `coeflegend` option to learn the names of the coefficients on the factor variables in the linear combination. As expected, the point estimates are the same as those reported by `regress`.

Next, we illustrate the effect of the two-step estimation problem if we calculate the potential-outcome means by hand. We can calculate the mean when no mothers smoke by accessing these coefficients and then estimate the standard errors in the estimated means:

```
. generate mean0 = _b[xb:0.mbsmoke] + _b[xb:0.mbsmoke#c.mage]*mage
> + _b[xb:0.mbsmoke#1.prenatal1]*prenatal1
. mean mean0
Mean estimation Number of obs = 4,642
```

|       | Mean     | Std. err. | [95% conf. interval] |          |
|-------|----------|-----------|----------------------|----------|
| mean0 | 3407.506 | 1.085503  | 3405.378             | 3409.634 |

The estimated potential-outcome mean for no mothers smoking is the same as that reported by margins, but the standard error is much smaller because mean ignores the estimation error in the coefficients. This underscores the importance of accounting for the estimation error when estimating the standard errors.

Now, we use gmm to estimate the coefficients and the potential-outcome means simultaneously.

```
. gmm (eq1: bweight - {xb:ibn.mbsmoke ibn.mbsmoke#{c.mage i.prenatal1}})
> (eq2: {xb:0.mbsmoke} + {xb:0bn.mbsmoke#c.mage}*mage
> + {xb:0bn.mbsmoke#1.prenatal1}*1.prenatal1 - {m0})
> (eq3: {xb:1.mbsmoke} + {xb:1.mbsmoke#c.mage}*mage
> + {xb:1.mbsmoke#1.prenatal1}*1.prenatal1 - {m1}),
> instruments(eq1: ibn.mbsmoke ibn.mbsmoke#{c.mage i.prenatal1},
> noconstant)
> instruments(eq2 eq3:) winitial(identity) onestep
```

Step 1:

This output has five noteworthy features.

1. We specify three different residual equations. The first, eq1:, defines the moment conditions for the regression using the covariates as instruments; eq2: is the moment condition for the potential outcome when no mothers smoke; and eq3: is the moment condition for the potential outcome when all mothers smoke.

2. In `eq2:` and `eq3:`, we refer to the individual coefficients on the factor variables in the linear combination `xb:` by enclosing their names in curly braces.
3. The `instruments()` option is repeatable. We first specify that the covariates in the regression are the instruments for the residual equation `eq1:` and then specify that only the unit variable, also known as the constant, is an instrument for each of `eq2:` and `eq3:`.
4. The point estimates and the standard errors match those reported by `regress` and `margins`, after accounting for the small-sample adjustment performed by `regress`.
5. Although the point estimates match, the standard errors reported by `gmm` are much larger than those reported by `mean` because `gmm` takes into account that the regression coefficients are estimated.

## Parameter interpretation using margins

In the last section, we demonstrated how to use `gmm` to estimate potential-outcome means in a linear regression model jointly with the coefficients of the models. However, you can also estimate the potential-outcome mean, or any other predictive margins, by using the `margins` command after `gmm`. Using `margins` after `gmm` can allow more flexibility in the predictive margins that we estimate and is also more convenient. See [Obtaining margins of responses](#) in [R] [margins](#) for more information about predictive margins.

### ▷ Example 5: Predicting treatment effects after estimation

In [example 4](#), we used `gmm` to estimate potential-outcome means of a mother's smoking behavior on her baby's birthweight (in grams) after controlling for age and whether she had a prenatal visit in the first trimester. Here we demonstrate how to use `margins` after `gmm` to estimate the potential-outcome means.

First, we load the data and reestimate the regression coefficients.

```

Now, we use margins to estimate the potential-outcome means. We specify `vce(unconditional)` to obtain standard errors for the potential-outcome means of the population rather than the sample. When we specify this option, the standard errors for the estimated means will account for the estimation error in the estimated coefficients from `gmm`.

```
. margins i.mbsmoke, vce(unconditional)
Predictive margins Number of obs = 4,642
Expression: Linear prediction, predict()
```

|           | Margin   | Unconditional<br>std. err. | z      | P> z  | [95% conf. interval] |          |
|-----------|----------|----------------------------|--------|-------|----------------------|----------|
| mbsmoke   |          |                            |        |       |                      |          |
| Nonsmoker | 3407.506 | 9.341858                   | 364.76 | 0.000 | 3389.196             | 3425.815 |
| Smoker    | 3138.23  | 21.19321                   | 148.08 | 0.000 | 3096.692             | 3179.768 |

Our point estimates of the potential-outcome means exactly match those that appear as  $\mu_0$  and  $\mu_1$  in [example 4](#). However, the standard errors are slightly higher because `gmm` and `margins` use different values in the denominator for the formula for the robust covariance matrix. `gmm` uses  $N$  while `margins` uses  $N - 1$ , so the standard errors differ by a factor of  $\sqrt{\{N/(N - 1)\}} = \sqrt{4,642/4,641} \approx 1.0002$ . More details about the calculation of the standard errors are provided in [Marginal predictions with unconditional standard errors](#) in the *Methods and formulas*.

In addition to potential-outcome means, we can use `margins` to estimate the average treatment effect (ATE) of the mother’s smoking behavior on birthweight. We use the contrast operator `r.` to instruct `margins` to difference the potential-outcome means and estimate a treatment effect. We specify the `contrast(nowald)` option to suppress the Wald test that `margins` displays by default for contrasts.

```
. margins r.mbsmoke, vce(unconditional) contrast(nowald)
Contrasts of predictive margins Number of obs = 4,642
Expression: Linear prediction, predict()
```

|                                  | Unconditional |           |                      |
|----------------------------------|---------------|-----------|----------------------|
|                                  | Contrast      | std. err. | [95% conf. interval] |
| mbsmoke<br>(Smoker vs Nonsmoker) | -269.2759     | 23.16069  | -314.67 -223.8818    |

The ATE of  $-269.28$  is interpreted as the difference between the average birthweight if all mothers in the population smoked and the average birthweight if all mothers in the population did not smoke. The average birthweight if all mothers were to smoke would be 269.28 grams less than if they did not smoke. ◀

## Exponential (Poisson) regression models

Exponential regression models are frequently encountered in applied work. For example, they can be used as alternatives to linear regression models on log-transformed dependent variables, obviating the need for post-hoc transformations to obtain predicted values in the original metric of the dependent variable. When the dependent variable represents a discrete count variable, exponential regression models are also known as Poisson regression models; see [Cameron and Trivedi \(2013\)](#).

For now, we consider models of the form

$$y = \exp(\mathbf{x}'\boldsymbol{\beta}) + u \quad (7)$$

where  $u$  is a zero-mean additive error term so that  $E(y) = \exp(\mathbf{x}'\boldsymbol{\beta})$ . Because the error term is additive, if  $\mathbf{x}$  represents strictly exogenous regressors, then we have the population moment condition

$$E[\mathbf{x}\{y - \exp(\mathbf{x}'\boldsymbol{\beta})\}] = \mathbf{0} \quad (8)$$

Moreover, because the number of parameters in the model is equal to the number of instruments, there is no point to using the two-step GMM estimator.

## ▷ Example 6: Exponential regression

Cameron and Trivedi (2022, 584) fit a model of the number of doctor visits based on whether the patient has private insurance, whether the patient has a chronic disease, gender, and income. Here we fit that model by using `gmm`. To allow for potential excess dispersion, we will obtain a robust VCE matrix, which is the default for `gmm` anyway. We type

```
. use https://www.stata-press.com/data/r19/docvisits
. gmm (docvis - exp({xb:private chronic female income _cons})),
> instruments(private chronic female income) onestep

Step 1:
Iteration 0: GMM criterion Q(b) = 16.853973
Iteration 1: GMM criterion Q(b) = 2.2706472
Iteration 2: GMM criterion Q(b) = .19088097
Iteration 3: GMM criterion Q(b) = .00041101
Iteration 4: GMM criterion Q(b) = 3.939e-09
Iteration 5: GMM criterion Q(b) = 6.572e-19
note: model is exactly identified.

GMM estimation
Number of parameters = 5
Number of moments = 5
Initial weight matrix: Unadjusted Number of obs = 4,412
```

|         | Coefficient | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |           |
|---------|-------------|---------------------|-------|-------|----------------------|-----------|
| private | .7986654    | .1089891            | 7.33  | 0.000 | .5850507             | 1.01228   |
| chronic | 1.091865    | .0559888            | 19.50 | 0.000 | .9821291             | 1.201601  |
| female  | .4925481    | .0585298            | 8.42  | 0.000 | .3778317             | .6072644  |
| income  | .003557     | .0010824            | 3.29  | 0.001 | .0014356             | .0056784  |
| _cons   | -.2297263   | .1108607            | -2.07 | 0.038 | -.4470093            | -.0124434 |

Instruments for equation 1: private chronic female income \_cons

Our point estimates agree with those reported by Cameron and Trivedi (2022) to at least six significant digits; the small discrepancies are attributable to different optimization techniques and convergence criteria being used by `gmm` and `poisson`. The standard errors differ by a factor of  $\sqrt{4412/4411}$  because `gmm` uses  $N$  in the denominator of the formula for the robust covariance matrix, while the robust covariance matrix estimator used by `poisson` uses  $N - 1$ .

◀

## □ Technical note

That the GMM and maximum likelihood estimators of the exponential regression model coincide is not a general property of these two classes of estimators. The maximum likelihood estimator solves the score equations

$$\frac{1}{N} \sum_{i=1}^N \frac{\partial \ln \ell_i}{\partial \beta} = \mathbf{0}$$

where  $\ell_i$  is the likelihood for the  $i$ th observation. These score equations can be viewed as the sample analogues of the population moment conditions

$$E \left( \frac{\partial \ln \ell_i}{\partial \beta} \right) = \mathbf{0}$$

establishing that maximum likelihood estimators represent a subset of the class of GMM estimators.

For the Poisson model,

$$\ln \ell_i = -\exp(\mathbf{x}'_i \boldsymbol{\beta}) + y_i \mathbf{x}'_i \boldsymbol{\beta} - \ln y_i!$$

so the score equations are

$$\frac{1}{N} \sum_{i=1}^N \mathbf{x}_i \{y_i - \exp(\mathbf{x}'_i \boldsymbol{\beta})\} = \mathbf{0}$$

which are just the sample moment conditions implied by (8) that we used in the [previous example](#). That is why our results using `gmm` match Cameron and Trivedi's (2022) results using `poisson`.

On the other hand, an intuitive set of moment conditions to consider for GMM estimation of a probit model is

$$E[\mathbf{x}\{y - \Phi(\mathbf{x}'\boldsymbol{\beta})\}] = \mathbf{0}$$

where  $\Phi(\cdot)$  is the standard normal cumulative distribution function. Differentiating the likelihood function for the maximum-likelihood probit estimator, we can show that the corresponding score equations are

$$\frac{1}{N} \sum_{i=1}^N \left[ \mathbf{x}_i \left\{ y_i \frac{\phi(\mathbf{x}'_i \boldsymbol{\beta})}{\Phi(\mathbf{x}'_i \boldsymbol{\beta})} - (1 - y_i) \frac{\phi(\mathbf{x}'_i \boldsymbol{\beta})}{1 - \Phi(\mathbf{x}'_i \boldsymbol{\beta})} \right\} \right] = \mathbf{0}$$

where  $\phi(\cdot)$  is the standard normal density function. These two moment conditions are not equivalent, so the maximum likelihood and GMM probit estimators are distinct. □

### ▷ Example 7: Comparison of GMM and maximum likelihood

Using the automobile dataset, we fit a probit model of `foreign` on `gear_ratio`, `length`, and `headroom` using first the score equations and then the intuitive set of GMM equations. We type

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. gmm (foreign*normalden({xb:gear_ratio length headroom _cons})/
> normal({xb:}) - (1-foreign)*normalden({xb:})/(1-normal({xb:}))),
> instruments(gear_ratio length headroom) onestep
(output omitted)
. estimates store ml
. gmm (foreign - normal({xb:gear_ratio length headroom _cons})),
> instruments(gear_ratio length headroom) onestep
(output omitted)
. estimates store gmm
. estimates table ml gmm, b se
```

| Variable   | ml                      | gmm                     |
|------------|-------------------------|-------------------------|
| gear_ratio | 2.9586277<br>.64042341  | 2.8489213<br>.63570247  |
| length     | -.02148933<br>.01382043 | -.02056033<br>.01396954 |
| headroom   | .01136927<br>.27278528  | .02240761<br>.2849891   |
| _cons      | -6.0222289<br>3.5594588 | -5.8595615<br>3.5188029 |

Legend: b/se

The coefficients on `gear_ratio` and `length` are close for the two estimators. The GMM estimate of the coefficient on `headroom` is twice that of the maximum likelihood estimate, though the relatively large standard errors imply that this difference is not significant. You can verify that the coefficients in the column marked “m1” match those you would obtain with `probit`. We have not discussed the differences among standard errors based on the various GMM and maximum-likelihood covariance matrix estimators to avoid tedious algebra. However, you can verify that the robust covariance matrix after one-step GMM estimation differs by only a finite-sample adjustment factor of  $(N/N - 1)$  from the robust covariance matrix reported by `probit`. Both the maximum likelihood and GMM `probit` estimators require the normality assumption, and the maximum likelihood estimator is efficient if that normality assumption is correct; therefore, in this example, there is no reason to prefer the GMM estimator.

◀

We can modify (8) easily to allow for endogenous regressors. Suppose that  $x_j$  is endogenous in the sense that  $E(u|x_j) \neq 0$ . Then, (8) is no longer a valid moment condition. However, suppose we have some variables other than  $\mathbf{x}$  such that  $E(u|\mathbf{z}) = \mathbf{0}$ . We can instead use the moment conditions

$$E(\mathbf{z}u) = E[\mathbf{z}\{y - \exp(\mathbf{x}'\boldsymbol{\beta})\}] = \mathbf{0}$$

As usual, if some elements of  $\mathbf{x}$  are exogenous, then they should appear in  $\mathbf{z}$  as well.

### ► Example 8: Exponential regression with endogenous regressors

Returning to the model discussed in [example 6](#), we treat `income` as endogenous; unobservable factors that determine a person’s income may also affect the number of times a person visits a doctor. We use a person’s age and race as instruments. These are valid instruments if we believe that age and race influence a person’s income but do not have a direct impact on the number of doctor visits. (Whether this belief is justified is another matter; we test that belief in [\[R\] gmm postestimation](#).) Because we have more instruments (seven) than parameters (five), we have an overidentified model. Therefore, the choice of weight matrix does matter. We will use the default two-step GMM estimator. In the first step, we will use a weight matrix that assumes the errors are i.i.d. In the second step, we will use a weight matrix that assumes heteroskedasticity. When you specify `twostep`, these are the defaults for the first- and second-step weight matrices, so we do not have to use the `winitial()` or `wmatrix()` options. We will again obtain a robust VCE, which is also the default. We type

```
. use https://www.stata-press.com/data/r19/docvisits
. gmm (docvis - exp({xb:private chronic female income _cons})),
> instruments(private chronic female age black hispanic) twostep
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = 16.910173
Iteration 1: GMM criterion Q(b) = .82276104
Iteration 2: GMM criterion Q(b) = .21832032
Iteration 3: GMM criterion Q(b) = .12685935
Iteration 4: GMM criterion Q(b) = .12672369
Iteration 5: GMM criterion Q(b) = .12672365
```

Step 2:

```
Iteration 0: GMM criterion Q(b) = .00234641
Iteration 1: GMM criterion Q(b) = .00215957
Iteration 2: GMM criterion Q(b) = .00215911
Iteration 3: GMM criterion Q(b) = .00215911
```

GMM estimation

Number of parameters = 5

Number of moments = 7

Initial weight matrix: Unadjusted

Number of obs = 4,412

GMM weight matrix: Robust

|         | Coefficient | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |          |
|---------|-------------|---------------------|-------|-------|----------------------|----------|
| private | .535335     | .1599039            | 3.35  | 0.001 | .2219291             | .8487409 |
| chronic | 1.090126    | .0617659            | 17.65 | 0.000 | .9690668             | 1.211185 |
| female  | .6636579    | .0959884            | 6.91  | 0.000 | .4755241             | .8517918 |
| income  | .0142855    | .0027162            | 5.26  | 0.000 | .0089618             | .0196092 |
| _cons   | -.5983477   | .138433             | -4.32 | 0.000 | -.8696713            | -.327024 |

Instruments for equation 1: private chronic female age black hispanic \_cons

Once we control for the endogeneity of income, we find that its coefficient has quadrupled in size. Additionally, access to private insurance has less of an impact on the number of doctor visits and gender has more of an impact.

◀

## □ Technical note

Although you may be tempted to try, you cannot, as you can in a Poisson model, replace  $\mathbf{x}$  in the moment conditions for the probit (or logit) model with a vector of instruments,  $\mathbf{z}$ , if you have endogenous regressors. See [Wilde \(2008\)](#).

□

[Mullahy \(1997\)](#) considers a slightly more complicated version of the exponential regression model that incorporates nonadditive unobserved heterogeneity. His model can be written as

$$y_i = \exp(\mathbf{x}'_i \boldsymbol{\beta}) \eta_i + \epsilon_i$$

where  $\eta_i > 0$  is an unobserved heterogeneity term that may be correlated with  $\mathbf{x}_i$ . One result from his article is that instead of using the additive moment condition (8), we can use the multiplicative moment condition

$$E \left\{ \mathbf{z} \frac{y - \exp(\mathbf{x}'\boldsymbol{\beta})}{\exp(\mathbf{x}'\boldsymbol{\beta})} \right\} = E[\mathbf{z}\{y\exp(-\mathbf{x}'\boldsymbol{\beta}) - 1\}] = \mathbf{0}$$

[Windmeijer and Santos Silva \(1997\)](#) discuss the use of additive versus multiplicative moment conditions with endogenous regressors and note that a set of instruments that satisfies the additive moment conditions will not also satisfy the multiplicative moment conditions. They remark that the decision about which to use is an empirical issue that can at least partially be settled by using the test of overidentifying restrictions that is implemented by `estat overid` after `gmm` to see whether the instruments for a given model are valid. See [\[R\] gmm postestimation](#) for information on the test of overidentifying restrictions.

## Specifying derivatives

By default, `gmm` calculates derivatives numerically, and the method used produces accurate results for the vast majority of applications. However, if you refit the same model repeatedly or else have the derivatives available, then `gmm` will run more quickly if you supply it with analytic derivatives.

When you use the interactive version of `gmm`, you specify derivatives using substitutable expressions in much the same way you specify the residual equations. There are three rules you must follow:

1. As with the substitutable expressions that define residual equations, you bind parameters of the model in curly braces: `{b0}`, `{param}`, etc.
2. You must specify a derivative for each parameter that appears in each residual equation. If a parameter does not appear in a residual equation, then you do not specify a derivative for that parameter in that residual equation.
3. If you declare a linear combination in an equation, then you specify a derivative with respect to that linear combination. `gmm` applies the chain rule to obtain the derivatives with respect to the individual parameters encompassed by that linear combination.

### ▷ Example 9: Derivatives for a single-equation model

Consider a simple exponential regression model with one exogenous regressor and a constant term. We have

$$u_i = y_i - \exp(\beta_0 + \beta_1 x_i)$$

Now,

$$\frac{\partial u_i}{\partial \beta_0} = -\exp(\beta_0 + \beta_1 x_i) \quad \text{and} \quad \frac{\partial u_i}{\partial \beta_1} = -x_i \exp(\beta_0 + \beta_1 x_i)$$

In Stata, we type

```
. gmm (docvis - exp({b0} + {b1}*income)), instruments(income)
> deriv(/b0 = -1*exp({b0} + {b1}*income))
> deriv(/b1 = -1*income*exp({b0}+{b1}*income)) onestep
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = 9.1548611
Iteration 1: GMM criterion Q(b) = 3.5146131
Iteration 2: GMM criterion Q(b) = .01344695
Iteration 3: GMM criterion Q(b) = 3.690e-06
Iteration 4: GMM criterion Q(b) = 4.606e-13
Iteration 5: GMM criterion Q(b) = 1.502e-26
```

note: model is exactly identified.

GMM estimation

Number of parameters = 2

Number of moments = 2

Initial weight matrix: Unadjusted

Number of obs = 4,412

|     | Robust      |           | z     | P> z  | [95% conf. interval] |          |
|-----|-------------|-----------|-------|-------|----------------------|----------|
|     | Coefficient | std. err. |       |       |                      |          |
| /b0 | 1.204888    | .0462355  | 26.06 | 0.000 | 1.114268             | 1.295507 |
| /b1 | .0046702    | .0009715  | 4.81  | 0.000 | .0027662             | .0065743 |

Instruments for equation 1: income\_cons

Notice how we specified the `derivative()` option for each parameter. We simply specified a slash, the name of the parameter, an equal sign, then a substitutable expression that represents the derivative. Because our model has only one residual equation, we do not need to specify equation numbers in the `derivative()` options.

When you specify a linear combination of variables, your derivative should be with respect to the entire linear combination. For example, say we have the residual equation

$$u_i = y - \exp(\mathbf{x}'_i\boldsymbol{\beta} + \beta_0)$$

for which we would type

```
. gmm (y - exp({xb: x1 x2 x3} + {b0})) ...
```

Then, in addition to the derivative  $\partial u_i/\partial\beta_0$ , we are to compute and specify

$$\frac{\partial u_i}{\partial \mathbf{x}'_i\boldsymbol{\beta}} = -\exp(\mathbf{x}'_i\boldsymbol{\beta} + \beta_0)$$

Using the chain rule,  $\partial u_i/\partial\beta_j = \partial u_i/\partial(\mathbf{x}'_i\boldsymbol{\beta}) \times \partial(\mathbf{x}'_i\boldsymbol{\beta})/\partial\beta_j = -x_{ij}\exp(\mathbf{x}'_i\boldsymbol{\beta} + \beta_0)$ . Stata does this last calculation automatically. It knows the variables in the linear combination, so all it needs is the derivative of the residual equation with respect to the linear combination. This allows you to change the variables in your linear combination without having to change the derivatives.

### ▷ Example 10: Derivatives with a linear combination

We refit the model described in the [example](#) illustrating exponential regression with endogenous regressors, now providing analytic derivatives. We type

```
. gmm (docvis - exp({xb:private chronic female income _cons})),
> instruments(private chronic female age black hispanic)
> derivative(/xb = -1*exp({xb:}))
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = 16.910173
Iteration 1: GMM criterion Q(b) = .82270871
Iteration 2: GMM criterion Q(b) = .21831995
Iteration 3: GMM criterion Q(b) = .12685934
Iteration 4: GMM criterion Q(b) = .12672369
Iteration 5: GMM criterion Q(b) = .12672365
```

Step 2:

```
Iteration 0: GMM criterion Q(b) = .00234641
Iteration 1: GMM criterion Q(b) = .00215957
Iteration 2: GMM criterion Q(b) = .00215911
Iteration 3: GMM criterion Q(b) = .00215911
```

GMM estimation

```
Number of parameters = 5
Number of moments = 7
Initial weight matrix: Unadjusted
GMM weight matrix: Robust
Number of obs = 4,412
```

|         | Robust      |           |       |       |                      |
|---------|-------------|-----------|-------|-------|----------------------|
|         | Coefficient | std. err. | z     | P> z  | [95% conf. interval] |

Instruments for equation 1: private chronic female age black hispanic \_cons

In the first `derivative()` option, we specified the name of the linear combination, `xb`, instead of an individual parameter's name. We already declared the variables of our linear combination in the substitutable expression for the residual equation, so in our substitutable expressions for the derivatives, we can use the shorthand notation `{xb:}` to refer to it.

Our point estimates are identical to those we obtained earlier. The standard errors and confidence intervals differ by only trivial amounts.

◀

## Exponential regression models with panel data

In addition to supporting cross-sectional and time-series data, `gmm` also works with panel-data models. Here we illustrate `gmm`'s panel-data capabilities by expanding our discussion of exponential regression models to allow for panel data. This also provides us the opportunity to demonstrate the moment-evaluator program version of `gmm`. Our discussion is based on [Blundell, Griffith, and Windmeijer \(2002\)](#). Also see [Wooldridge \(1999\)](#) for further discussion of nonlinear panel-data models.

First, we expand (7) for panel data. With individual heterogeneity term  $\eta_i$ , we have

$$E(y_{it} | \mathbf{x}_{it}, \eta_i) = \exp(\mathbf{x}'_{it}\boldsymbol{\beta} + \eta_i) = \mu_{it}\nu_i$$

where  $\mu_{it} = \exp(\mathbf{x}'_{it}\boldsymbol{\beta})$  and  $\nu_i = \exp(\eta_i)$ . Note that there is no constant term in this model, because its effect cannot be disentangled from  $\nu_i$ . With an additive idiosyncratic error term, we have the regression model

$$y_{it} = \mu_{it}\nu_i + \epsilon_{it}$$

We do not impose the assumption  $E(\mathbf{x}_{it}\eta_i) = \mathbf{0}$ , so  $\eta_i$  can be considered a fixed effect in the sense that it may be correlated with the regressors.

As discussed by [Blundell, Griffith, and Windmeijer \(2002\)](#), if  $\mathbf{x}_{it}$  is strictly exogenous, meaning  $E(\mathbf{x}_{it}\epsilon_{is}) = \mathbf{0}$  for all  $t$  and  $s$ , then we can estimate the parameters of the model by using the sample moment conditions

$$\sum_i \sum_t \mathbf{x}_{it} \left( y_{it} - \mu_{it} \frac{\bar{y}_i}{\bar{\mu}_i} \right) = \mathbf{0} \quad (9)$$

where  $\bar{y}_i$  and  $\bar{\mu}_i$  are the means of  $y_{it}$  and  $\mu_{it}$  for panel  $i$ , respectively. Because  $\bar{\mu}_i$  depends on the parameters of the model, it must be recomputed each time `gmm` needs to evaluate the residual equation. Therefore, we cannot use the substitutable expression version of `gmm`. Instead, we must use the moment-evaluator program version.

The moment-evaluator program version of gmm functions much like the function-evaluator program versions of nl and nlsur. The program you write is passed one or more variables to be filled in with the residuals evaluated at the parameter values specified in an option passed to your program. For the fixed-effects Poisson model with strictly exogenous regressors, our first crack at a function-evaluator program is

```

program gmm_poi
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name)
 quietly {
 tempvar mu mubar ybar
 generate double `mu' = exp(x1*`at'[1,1] + x2*`at'[1,2] ///
 + x3*`at'[1,3]) `if'
 egen double `mubar' = mean(`mu') `if', by(id)
 egen double `ybar' = mean(y) `if', by(id)
 replace `varlist' = y - `mu'*`ybar'/'mubar' `if'
 }
end

```

You can save your program in an ado-file named *name*.ado, where *name* is the name you use for your program; here we would save the program in the ado-file `gmm_poi.ado`. Alternatively, if you are working from within a do-file, you can simply define the program before calling `gmm`. The `syntax` statement declares we are expecting to receive *varlist* that will contain the names of variables whose values we are to replace with the values of the residual equations and an `if` expression that will mark the estimation sample; because our model has one residual equation, *varlist* will consist of one variable. `at()` is a required option to our program, and it will contain the name of a matrix containing the parameter values at which we are to evaluate the residual equation. All moment-evaluator programs must accept the *varlist*, `if` condition, and `at()` option.

The first part of our program computes  $\mu_{it}$ . In the model we will fit shortly, we have three regressors, named `x1`, `x2`, and `x3`. The `'at'` vector will have three elements, one for each of those variables. Notice that we included `'if'` at the end of each statement that affects variables to restrict the computations to the relevant estimation sample. The two `egen` statements compute  $\bar{\mu}_i$  and  $\bar{y}_i$ ; in the example dataset we will use shortly, the panel variable is named `id`, and for simplicity, we hardcoded that variable into our program as well. Finally, we compute the residual equation, which is the portion of (9) bound in parentheses.

### ► Example 11: Panel Poisson with strictly exogenous regressors

To fit our model, we type

```

. use https://www.stata-press.com/data/r19/poisson1
. gmm gmm_poi, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep

Step 1:
Iteration 0: GMM criterion Q(b) = 51.99142
Iteration 1: GMM criterion Q(b) = .04345191
Iteration 2: GMM criterion Q(b) = 8.720e-06
Iteration 3: GMM criterion Q(b) = 7.115e-13
Iteration 4: GMM criterion Q(b) = 5.130e-27

note: model is exactly identified.

```

## GMM estimation

Number of parameters = 3

Number of moments = 3

Initial weight matrix: Unadjusted

Number of obs = 409

(Std. err. adjusted for 45 clusters in id)

|     | Coefficient | Robust<br>std. err. | z      | P> z  | [95% conf. interval] |           |
|-----|-------------|---------------------|--------|-------|----------------------|-----------|
| /b1 | 1.94866     | .1000265            | 19.48  | 0.000 | 1.752612             | 2.144709  |
| /b2 | -2.966119   | .0923592            | -32.12 | 0.000 | -3.14714             | -2.785099 |
| /b3 | 1.008634    | .1156561            | 8.72   | 0.000 | .781952              | 1.235315  |

Instruments for equation 1: x1 x2 x3

All three of our regressors are strictly exogenous, so they can serve as their own regressors. There is no constant term in the model (it would be unidentified), so we exclude a constant term from our list of instruments. We have one residual equation as indicated by `nequations(1)`, and we have three parameters, named `b1`, `b2`, and `b3`. The order in which you declare parameters in the `parameters()` option determines the order in which they appear in the ‘at’ vector in the moment-evaluator program. We specified `vce(cluster id)` to obtain standard errors that allow for correlation among observations within each panel.

◀

The program we just wrote is sufficient to fit the model to the `poisson1` dataset, but if we want to fit that model to other datasets, we need to change the variable names and perhaps account for having a different number of parameters as well. Despite those limitations, if you just want to fit a single model, that program is adequate.

Next, we take advantage of the ability to specify full equation names in the `parameters()` option and rewrite our evaluator program so that we can more easily change the variables in our model. This approach is particularly useful if some of the residual equations are linear in the parameters because then we can use `matrix score` (see [P] [matrix score](#)) to evaluate those moments.

Our new evaluator program is

```

program gmm_poieq
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name)
 quietly {
 tempvar mu mubar ybar
 matrix score double `mu' = `at' `if', eq(#1)
 replace `mu' = exp(`mu')
 egen double `mubar' = mean(`mu') `if', by(id)
 egen double `ybar' = mean(y) `if', by(id)
 replace `varlist' = y - `mu'*`ybar'/'mubar' `if'
 }
end

```

Rather than using `generate` to compute the temporary variable ‘mu’, we used `matrix score` to obtain the linear combination  $\mathbf{x}'_{it}\beta$  and then called `replace` to compute  $\exp(\mathbf{x}'_{it}\beta)$ .

Typing

```
. matrix score double eq1 = 'at', eq(#1)
```

is equivalent to typing

```
. generate double eq1 = x1*'at'[1,1] + x2*'at'[1,2] + 'at'[1,3]
```

with one important difference. If we change some of the variables in the `parameters()` option when we call `gmm`, `matrix score` will compute the correct linear combination. If we were to use the `generate` statement instead, then every time we wanted to change the variables in our model, we would have to modify that statement as well.

The command

```
. matrix score double alpha = 'at', eq(#2)
```

is equivalent to

```
. scalar alpha = 'at'[1,4]
```

Thus, even if you specify linear combination and variable names in the `parameters()` option, you can still have scalar parameters in your model. □

When past values of the idiosyncratic error term affect the value of a regressor, we say that regressor is predetermined. When one or more regressors are predetermined, sample moment condition (8) is no longer valid. However, [Chamberlain \(1992\)](#) shows that a simple alternative is to consider moment conditions of the form

$$\sum_i \sum_{t=2}^T \mathbf{x}_{i,t-1} \left( y_{i,t-1} - \mu_{i,t-1} \frac{y_{it}}{\mu_{it}} \right) = \mathbf{0} \quad (10)$$

Also see [Wooldridge \(1997\)](#) and [Windmeijer \(2000\)](#) for other moment conditions that can be used with predetermined regressors.

### ▷ Example 13: Panel Poisson with predetermined regressors

Here we refit the previous model, treating all the regressors as predetermined and using the moment conditions in (10). Our moment-evaluator program is

```
program gmm_poipre
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name) mylhs(varlist)
 quietly {
 tempvar mu
 matrix score double 'mu' = 'at' 'if', eq(#1)
 replace 'mu' = exp('mu')
 replace 'varlist' = L.'mylhs' - L.'mu'*'mylhs'/'mu' 'if'
 }
end
```

To compute the residual equation, we used lag-operator notation so that Stata properly handles gaps in our panel dataset. We also made our program accept an additional option that we will use to pass in the dependent variable. When we specify this option in our `gmm` statement, it will get passed to our evaluator program because `gmm` will not recognize the option as one of its own. Equation (10) shows that we are to use the first lags of the regressors as instruments, so we type

```
. gmm gmm_poipre, mylhs(y) nequations(1) vce(cluster id) onestep
> parameters({y:x1 x2 x3}) instruments(L.(x1 x2 x3), noconstant)
note: 45 missing values returned for equation 1 at initial values.
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = 76.652367
Iteration 1: GMM criterion Q(b) = 1.9118192
Iteration 2: GMM criterion Q(b) = .06634724
Iteration 3: GMM criterion Q(b) = .0000233
Iteration 4: GMM criterion Q(b) = 2.998e-12
Iteration 5: GMM criterion Q(b) = 4.888e-26
```

note: model is exactly identified.

GMM estimation

Number of parameters = 3

Number of moments = 3

Initial weight matrix: Unadjusted

Number of obs = 364

(Std. err. adjusted for 45 clusters in id)

|    | Robust      |           | z      | P> z  | [95% conf. interval] |           |
|----|-------------|-----------|--------|-------|----------------------|-----------|
|    | Coefficient | std. err. |        |       |                      |           |
| x1 | 2.088246    | .2513626  | 8.31   | 0.000 | 1.595584             | 2.580907  |
| x2 | -2.905504   | .2133908  | -13.62 | 0.000 | -3.323742            | -2.487266 |
| x3 | 1.121081    | .201654   | 5.56   | 0.000 | .7258459             | 1.516315  |

Instruments for equation 1: L.x1 L.x2 L.x3

Here, like earlier with strictly exogenous regressors, the number of instruments equals the number of parameters, so there is no gain to using the two-step or iterated estimator. However, if you do have more instruments than parameters, you will most likely want to use one of those other estimators instead.

The note at the top of the output is given because we have 45 panels in our dataset. Our residual equation includes lagged terms and therefore cannot be evaluated for the first time period within each panel. Notes like this can be ignored once you know why they occurred. If you receive a note that you were not expecting, you should first investigate the cause of the note before trusting the results.

Instead of making our program accept the `mylhs()` option, we could have used Stata's `coleq` macro function to determine the dependent variable based on the column names attached to the 'at' vector; see [\[P\] macro](#). Then, we could refit our model with a different dependent variable by changing the `lname` used in the `parameters()` option. In the [next example](#), we take this approach.

◀

In the [previous example](#), we used  $\mathbf{x}_{i,t-1}$  as instruments. A more efficient GMM estimator would also use  $\mathbf{x}_{i,t-2}, \mathbf{x}_{i,t-3}, \dots, \mathbf{x}_{i,1}$  as instruments in period  $t$  as well. `gmm`'s `xtinstruments()` option allows you to specify instrument lists that grow as  $t$  increases. Later, we discuss the `xtinstruments()` option in detail in the context of linear dynamic panel-data models.

When a regressor is contemporaneously correlated with the idiosyncratic error term, we say that regressor is endogenous. [Windmeijer \(2000\)](#) shows that we can use the moment condition

$$\sum_i \sum_{t=3}^T \mathbf{x}_{i,t-2} \left( \frac{y_{it}}{\mu_{it}} - \frac{y_{i,t-1}}{\mu_{i,t-1}} \right)$$

Here we use the second lag of the endogenous regressor as an instrument. If a variable is strictly exogenous, it can of course serve as its own instrument.

## ▶ Example 14: Panel Poisson with endogenous regressors

Here we refit the model, treating  $x_3$  as endogenous and  $x_1$  and  $x_2$  as strictly exogenous. Our moment-evaluator program is

```

program gmm_poiend
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name)
 quietly {
 tempvar mu
 matrix score double `mu' = `at' `if', eq(#1)
 replace `mu' = exp(`mu')
 local mylhs : coleq `at'
 local mylhs : word 1 of `mylhs'
 replace `varlist' = `mylhs'/'mu' - L.`mylhs'/L.`mu' `if'
 }
end

```

Now, we call `gmm` using  $x_1$ ,  $x_2$ , and `L2.x3` as instruments:

```

. use https://www.stata-press.com/data/r19/poisson2
. gmm gmm_poiend, nequations(1) vce(cluster id) onestep
> parameters(y:x1 y:x2 y:x3) instruments(x1 x2 L2.x3, noconstant)
note: 500 missing values returned for equation 1 at initial values.

Step 1:
Iteration 0: GMM criterion Q(b) = 61.832288
Iteration 1: GMM criterion Q(b) = .03402584
Iteration 2: GMM criterion Q(b) = .01101288
Iteration 3: GMM criterion Q(b) = 6.339e-06
Iteration 4: GMM criterion Q(b) = 1.620e-12
Iteration 5: GMM criterion Q(b) = 1.312e-25

note: model is exactly identified.

GMM estimation
Number of parameters = 3
Number of moments = 3
Initial weight matrix: Unadjusted
 Number of obs = 3,766
 (Std. err. adjusted for 500 clusters in id)

```

|    | Coefficient | Robust<br>std. err. | z      | P> z  | [95% conf. interval] |           |
|----|-------------|---------------------|--------|-------|----------------------|-----------|
| x1 | 1.8141      | .2688318            | 6.75   | 0.000 | 1.2872               | 2.341001  |
| x2 | -2.982671   | .1086666            | -27.45 | 0.000 | -3.195653            | -2.769688 |
| x3 | 4.126518    | 6.369334            | 0.65   | 0.517 | -8.357147            | 16.61018  |

Instruments for equation 1: x1 x2 L2.x3

The note at the top of the output is given because that we have 500 panels in our dataset. As in the [previous example](#), our residual equation includes lagged terms and therefore cannot be evaluated for the first time period within each panel. Instead of using just  $x_{i,t-2}$  as an instrument, we could use all further lags of  $x_{it}$  as instruments as well.

## Rational-expectations models

Macroeconomic models typically assume that agents' expectations about the future are formed rationally. By rational expectations, we mean that agents use all information available when forming their forecasts, so the forecast error is uncorrelated with the information available when the forecast was made. Say that at time  $t$ , people make a forecast,  $\hat{y}_{t+1}$ , of variable  $y$  in the next period. If  $\Omega_t$  denotes all available information at time  $t$ , then rational expectations implies that  $E\{(\hat{y}_{t+1} - y_{t+1})|\Omega_t\} = 0$ . If  $\Omega_t$  denotes observable variables such as interest rates or prices, then this conditional expectation can serve as the basis of a moment condition for GMM estimation.

### ▷ Example 15: Fitting a Euler equation

In a well-known article, [Hansen and Singleton \(1982\)](#) consider a model of portfolio decision making and discuss parameter estimation using GMM. We will consider a simple example with one asset in which the agent can invest. A consumer wants to maximize the present value of his or her lifetime utility derived from buying a good. On the one hand, the consumer is impatient, so he or she would rather buy today than wait until tomorrow. On the other hand, by buying less today, the consumer can invest more money, earning more interest that can be used to buy more of the good tomorrow. Thus, there is a tradeoff between having cake today or sacrificing a bit today to have more cake tomorrow.

If we assume a specific form for the agent's utility function, known as the constant relative-risk aversion utility function, we can show that the Euler equation is

$$E[\mathbf{z}_t \{1 - \beta(1 + r_{t+1})(c_{t+1}/c_t)^{-\gamma}\}] = \mathbf{0}$$

where  $\beta$  and  $\gamma$  are the parameters to estimate,  $r_t$  is the return to the financial asset, and  $c_t$  is consumption in period  $t$ .  $\beta$  measures the agent's discount factor. If  $\beta$  is near 1, the agent is patient and is more willing to forgo consumption this period. If  $\beta$  is close to 0, the agent is less patient and prefers to consume more now. The parameter  $\gamma$  characterizes the agent's utility function. If  $\gamma = 0$ , the utility function is linear. As  $\gamma$  tends toward 1, the utility function tends toward  $u = \log(c)$ .

We have data on three-month Treasury bills ( $r_t$ ) and consumption expenditures ( $c_t$ ). As instruments, we will use lagged rates of return and past growth rates of consumption. We will use the two-step estimator and a weight matrix that allows for heteroskedasticity and autocorrelation up to four lags with the Bartlett kernel. In Stata, we type

HAC standard errors based on Bartlett kernel with 4 lags.  
 Instruments for equation 1: L.r L2.r cgrowth L.cgrowth\_cons

The note at the top of the output is given because the forward operator in our substitutable expression says that residuals cannot be computed for the last observation. In addition, two observations are omitted because the L2.r instrument has missing values in the first two time periods. Therefore, of the 242 observations in our dataset, 239 are used to fit the model. Our estimate of  $\beta$  is near 1, in line with expectations and published results. However, our estimate of  $\gamma$  implies risk-loving behavior and therefore a poorly specified model.

Also notice our use of the forward operator to refer to the values of  $r$  and  $c$  one period ahead; time-series operators are allowed in substitutable expressions as long as you have previously `tsset` (see [TS] `tsset`) your data. See [U] 13.10 Time-series operators for more information on time-series operators.

◀

## System estimators

In many economic models, two or more variables are determined jointly through a system of simultaneous equations. Indeed, some of the earliest work in econometrics, including that of the Cowles Commission, was centered around estimation of the parameters of simultaneous equations. The 2SLS and

instrumental-variables estimators we have already discussed are used in some circumstances to estimate such parameters. Here we focus on the joint estimation of all the parameters of systems of equations, and we begin with the well-known three-stage least-squares (3SLS) estimator.

Recall that the 2SLS estimator is based on the moment conditions  $E(\mathbf{z}\mathbf{u}) = \mathbf{0}$ . The 2SLS estimator can be used to estimate the parameters of one equation of a system of structural equations. Moreover, with the 2SLS estimator, we do not even need to specify the structural relationship among all the endogenous variables; we need to specify only the equation on which interest focuses and simply assume reduced-form relationships among the endogenous regressors of the equation of interest and the exogenous variables of the model. If we are willing to specify the complete system of structural equations, then assuming our model is correctly specified, by estimating all the equations jointly, we can obtain estimates that are more efficient than equation-by-equation 2SLS.

In [R] **reg3**, we fit a simple two-equation macroeconomic model,

$$\text{consump} = \beta_0 + \beta_1 \text{wagepriv} + \beta_2 \text{wagegovt} + \epsilon_1 \quad (11)$$

$$\text{wagepriv} = \beta_3 + \beta_4 \text{consump} + \beta_5 \text{govt} + \beta_6 \text{capital1} + \epsilon_2 \quad (12)$$

where `consump` represents aggregate consumption; `wagepriv` and `wagegovt` are total wages paid by the private and government sectors, respectively; `govt` is government spending; and `capital1` is the previous period's capital stock. We are not willing to assume that  $\epsilon_1$  and  $\epsilon_2$  are independent, so we must treat both `consump` and `wagepriv` as endogenous. Suppose that a random shock makes  $\epsilon_2$  positive. Then by (12), `wagepriv` will be higher than it otherwise would. Moreover,  $\epsilon_1$  will be either higher or lower, depending on the correlation between it and  $\epsilon_2$ . The shock to  $\epsilon_2$  has made both `wagepriv` and  $\epsilon_1$  move, which implies that in (11), `wagepriv` is an endogenous regressor. A similar argument shows that `consump` is an endogenous regressor in the second equation. In our model, `wagegovt`, `govt`, and `capital1` are all exogenous variables.

Let  $\mathbf{z}_1$  and  $\mathbf{z}_2$  denote the instruments for the first and second equations, respectively; we will discuss what comprises them shortly. We have two sets of moment conditions:

$$E \left\{ \begin{array}{l} \mathbf{z}_1 (\text{consump} - \beta_0 - \beta_1 \text{wagepriv} - \beta_2 \text{wagegovt}) \\ \mathbf{z}_2 (\text{wagepriv} - \beta_3 - \beta_4 \text{consump} - \beta_5 \text{govt} - \beta_6 \text{capital1}) \end{array} \right\} = \mathbf{0} \quad (13)$$

One of the defining characteristics of 3SLS is that the errors are homoskedastic conditional on the instrumental variables. Using this assumption, we have

$$E \left[ \begin{array}{l} \left\{ \begin{array}{l} \mathbf{z}_1 \epsilon_1 \\ \mathbf{z}_2 \epsilon_2 \end{array} \right\} \left\{ \begin{array}{ll} \mathbf{z}'_1 \epsilon_1 & \mathbf{z}'_2 \epsilon_2 \end{array} \right\} \end{array} \right] = \begin{array}{cc} \left\{ \begin{array}{ll} \sigma_{11} E(\mathbf{z}_1 \mathbf{z}'_1) & \sigma_{12} E(\mathbf{z}_1 \mathbf{z}'_2) \\ \sigma_{21} E(\mathbf{z}_2 \mathbf{z}'_1) & \sigma_{22} E(\mathbf{z}_2 \mathbf{z}'_2) \end{array} \right\} \end{array} \quad (14)$$

where  $\sigma_{ij} = \text{cov}(\epsilon_i, \epsilon_j)$ . Let  $\Sigma$  denote the  $2 \times 2$  matrix with typical element  $\sigma_{ij}$ .

The second defining characteristic of the 3SLS estimator is that it uses all the exogenous variables as instruments for all equations; here  $\mathbf{z}_1 = \mathbf{z}_2 = (\text{wagegovt}, \text{govt}, \text{capital1}, 1)$ , where the 1 indicates a constant term. From our discussion on the weight matrix and two-step estimation, we want to use the sample analogue of the matrix inverse of the right-hand side of (14) as our weight matrix.

To implement the 3SLS estimator, we apparently need to know  $\Sigma$  or at least have a consistent estimator of it. The solution is to fit (11) and (12) by 2SLS, use the sample residuals  $\widehat{\epsilon}_1$  and  $\widehat{\epsilon}_2$  to estimate  $\Sigma$ , then estimate the parameters of (13) via GMM by using the weight matrix just discussed.

### ► Example 16: 3SLS estimation

3SLS is easier to do using `gmm` than it sounds. The 3SLS estimator is a two-step GMM estimator. In the first step, we do the equivalent of 2SLS on each equation, and then we compute a weight matrix based on (14). Finally, we perform a second step of GMM with this weight matrix.

In Stata, we type

```
. use https://www.stata-press.com/data/r19/klein, clear
. gmm (eq1: consump - {xb: wagepriv wagegovt _cons})
> (eq2: wagepriv - {xc: consump govt capital1 _cons}),
> instruments(eq1: wagegovt govt capital1)
> instruments(eq2: wagegovt govt capital1)
> winitial(unadjusted, independent) wmatrix(unadjusted) twostep

Step 1:
Iteration 0: GMM criterion Q(b) = 4195.4487
Iteration 1: GMM criterion Q(b) = .22175631
Iteration 2: GMM criterion Q(b) = .22175631 (backed up)

Step 2:
Iteration 0: GMM criterion Q(b) = .09716589
Iteration 1: GMM criterion Q(b) = .07028208
Iteration 2: GMM criterion Q(b) = .07028208

GMM estimation

```
Instruments for equation eq1: wagegovt govt capital1 _cons
Instruments for equation eq2: wagegovt govt capital1 _cons
```

The independent suboption of the `winitial()` option tells `gmm` to assume that the residuals are independent across moment conditions; this suboption sets  $\sigma_{21} = \sigma_{12} = 0$  in (14). Assuming both homoskedasticity and cross-equation independence is equivalent to fitting the two equations of our model independently by 2SLS. The `wmatrix()` option controls how the weight matrix is computed on the basis of the first-step parameter estimates before the second step of estimation; here we request a weight matrix that assumes conditional homoskedasticity but that does not impose the cross-equation independence like the initial weight matrix we used. In this example, we also illustrated how to name residual equations and how equation names can be used in the `instruments()` option. Our results are identical to those in [R] `reg3`.

We could have specified our instruments with the syntax

```
instruments(wagegovt govt capital1)
```

because `gmm` uses the variables listed in the `instruments()` option for all equations unless you specify which equations the list of instruments is to be used with. However, we wanted to emphasize that the same instruments are being used for both equations; in a moment, we will discuss an estimator that does not use the same instruments in all equations. ◀

In the [previous example](#), if we omit the `twostep` option, the resulting coefficients will be equivalent to equation-by-equation 2SLS, which [Wooldridge \(2010, 216\)](#) calls the “system 2SLS estimator”. Eliminating the `twostep` option makes the `wmatrix()` option irrelevant, so that option can be eliminated as well.

So far, we have developed the traditional 3SLS estimator. [Wooldridge \(2010, chap. 8\)](#) discusses the “GMM 3SLS” estimator, which extends the traditional 3SLS estimator by allowing for heteroskedasticity and different instruments for different equations.

Generalizing (14) to an arbitrary number of equations, we have

$$E(\mathbf{Z}'\epsilon\epsilon'\mathbf{Z}) = E(\mathbf{Z}'\Sigma\mathbf{Z}) \quad (15)$$

where

$$\mathbf{Z} = \begin{bmatrix} \mathbf{z}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{z}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{z}_m \end{bmatrix}$$

and  $\Sigma$  is now  $m \times m$ . Equation (15) is the multivariate analogue of a homoskedasticity assumption; for each equation, the error variance is constant for all observations, as is the covariance between any two equations’ errors.

We can relax this homoskedasticity assumption by considering different weight matrices. For example, if we continue to assume that observations are independent but not necessarily identically distributed, then by specifying `wmatrix(robust)`, we would obtain a weight matrix that allows for heteroskedasticity:

$$\widehat{W} = \frac{1}{N} \sum_i \mathbf{z}'_i \widehat{\epsilon}_i \widehat{\epsilon}'_i \mathbf{z}_i$$

This is the weight matrix in [Wooldridge’s \(2010, 218\) Procedure 8.1](#), “GMM with Optimal Weighting Matrix”. By default, `gmm` would report standard errors based on his covariance matrix (8.27); specifying `vce(unadjusted)` would provide the optimal GMM standard errors. If you have multiple observations for each individual or firm in your dataset, you could specify `wmatrix(cluster id)`, where `id` identifies individuals or firms. This would allow arbitrary within-individual correlation, though it does not account for an individual-specific fixed or random effect. In both cases, we would continue to use `winitial(unadjusted, independent)` so that the first-step estimates are the system 2SLS estimates.

[Wooldridge \(2010, sec. 9.6\)](#) discusses instances where it is necessary to use different instruments in different equations. The GMM 3SLS estimator with different instruments in different equations but with conditional homoskedasticity is what [Hayashi \(2000, 275\)](#) calls the “full-information instrumental-variables efficient” (FIVE) estimator. Implementing the FIVE estimator is easy with `gmm`. For example, say we have a two-equation system where `kids`, `age`, `income`, and `education` are all valid instruments for the first equation but where `education` is not a valid instrument for the second equation. Then, our syntax would take the form

```
gmm (exp_1) (exp_2), instruments(1:kids age income education) ///
instruments(2:kids age income)
```

The following syntax is equivalent:

```
gmm (exp_1) (exp_2), instruments(kids age income)
instruments(1:education)
```

Because we did not specify a list of equations in the second example's first `instruments()` option, those variables are used as instruments in both equations. You can use whichever syntax you prefer. The first requires a bit more typing but is arguably more transparent.

If all the regressors in the model are exogenous, then the traditional 3SLS estimator is the seemingly unrelated regression (SUR) estimator. Here you would specify all the regressors as instruments.

## Dynamic panel-data models

Commands in Stata that work with panel data expect the data to be in the “long” format, meaning that each row of the dataset consists of one subobservation that is a member of a logical observation (represented by the panel identifier variable). See [D] [reshape](#) for a discussion of the long versus “wide” data forms. `gmm` is no exception in this respect when used with panel data. From a theoretical perspective, however, it is sometimes easier to view GMM estimators for panel data as system estimators in which we have  $N$  observations on a system of  $T$  equations, where  $N$  and  $T$  are the number of observations and panels, respectively, rather than a single-equation estimator with  $NT$  observations. Usually, each of the  $T$  equations will in fact be the same, though we will want to specify different instruments for each of these equations.

In a dynamic panel-data model, lagged values of the dependent variable are included as regressors. Here we consider a simple model with one lag of the dependent variable  $y$  as a regressor and a vector of strictly exogenous regressors,  $\mathbf{x}_{it}$ :

$$y_{it} = \rho y_{i,t-1} + \mathbf{x}'_{it}\boldsymbol{\beta} + u_i + \epsilon_{it} \quad (16)$$

$u_i$  can be either a fixed- or a random-effect term in the sense that we do not require  $\mathbf{x}_{it}$  to be independent of it. Even with the assumption that  $\epsilon_{it}$  is i.i.d., the presence of both  $y_{i,t-1}$  and  $u_i$  in (16) renders both the standard fixed- and random-effects estimators to be inconsistent because of the well-known [Nickell \(1981\)](#) bias. OLS regression of  $y_{it}$  on  $y_{i,t-1}$  and  $\mathbf{x}_{it}$  also produces inconsistent estimates because  $y_{i,t-1}$  will be correlated with the error term.

### □ Technical note

Stata has the `xtabond`, `xtdpd`, and `xtdpdsys` commands (see [XT] [xtabond](#), [XT] [xtdpd](#), and [XT] [xtdpdsys](#)) to fit equations like (16); for everyday use, those commands are preferred because they offer features such as [Windmeijer \(2005\)](#) bias-corrected standard errors to account for the bias of traditional two-step GMM standard errors seen in dynamic panel-data models and, being linear estimators, only require you to specify variable names instead of complete equations. However, using `gmm` has several pedagogical advantages, including the ability to tie those model-specific commands into a more general framework, a clear illustration of how certain types of instrument matrices for panel-data models are formed, and demonstrations of several advanced features of `gmm`. □

First-differencing (16) removes the panel-specific  $u_i$  term:

$$y_{it} - y_{i,t-1} = \rho(y_{i,t-1} - y_{i,t-2}) + (\mathbf{x}_{it} - \mathbf{x}_{i,t-1})'\boldsymbol{\beta} + (\epsilon_{it} - \epsilon_{i,t-1}) \quad (17)$$

However, now  $(y_{i,t-1} - y_{i,t-2})$  is correlated with  $(\epsilon_{it} - \epsilon_{i,t-1})$ . Thus, we need an instrument that is correlated with the former but not the latter. The lagged variables in (17) mean that the equation is not estimable for  $t < 3$ , so consider when  $t = 3$ . We have

$$y_{i3} - y_{i2} = \rho(y_{i2} - y_{i1}) + (\mathbf{x}_{i3} - \mathbf{x}_{i2})' \boldsymbol{\beta} + (\epsilon_{i3} - \epsilon_{i2}) \tag{18}$$

In the Arellano–Bond (1991) estimator, lagged levels of the dependent variable are used as instruments. With our assumption that the  $\epsilon_{it}$  are i.i.d., (16) intimates that  $y_{i1}$  can serve as an instrumental variable when we fit (18).

Next, consider (17) when  $t = 4$ . We have

$$y_{i4} - y_{i3} = \rho(y_{i3} - y_{i2}) + (\mathbf{x}_{i4} - \mathbf{x}_{i3})' \boldsymbol{\beta} + (\epsilon_{i4} - \epsilon_{i3})$$

Now, (16) shows that both  $y_{i1}$  and  $y_{i2}$  are uncorrelated with the error term  $(\epsilon_{i4} - \epsilon_{i3})$ , so we have two instruments available. For  $t = 5$ , you can show that  $y_{i1}$ ,  $y_{i2}$ , and  $y_{i3}$  can serve as instruments. As may now be apparent, one of the key features of these dynamic panel-data models is that the available instruments depend on the time period,  $t$ , as was the case for some of the panel Poisson models we considered earlier. Because the  $\mathbf{x}_{it}$  are strictly exogenous by assumption, they can serve as their own instruments.

The initial weight matrix that is appropriate for the GMM dynamic panel-data estimator is slightly more involved than the unadjusted matrix that we have used in most of our previous examples and that assumes the errors are i.i.d. First, rewrite (17) for panel  $i$  as

$$\mathbf{y}_i - \mathbf{y}_i^L = \rho(\mathbf{y}_i^L - \mathbf{y}_i^{LL}) + (\mathbf{X}_i - \mathbf{X}_i^L) \boldsymbol{\beta} + (\boldsymbol{\epsilon}_i - \boldsymbol{\epsilon}_i^L)$$

where  $\mathbf{y}_i = (y_{i3}, \dots, y_{iT})$  and  $\mathbf{y}_i^L = (y_{i2}, \dots, y_{i,T-1})$ ,  $\mathbf{y}_i^{LL} = (y_{i1}, \dots, y_{i,T-2})$ , and  $\mathbf{X}_i, \mathbf{X}_i^L, \boldsymbol{\epsilon}_i$ , and  $\boldsymbol{\epsilon}_i^L$  are defined analogously. Let  $\mathbf{Z}$  denote the full matrix of instruments for panel  $i$ , including the variables specified in both the `instruments()` and `xtinstruments()` options; the exact structure is detailed in [Methods and formulas](#).

By assumption,  $\epsilon_{it}$  is i.i.d., so the first difference  $(\epsilon_{it} - \epsilon_{i,t-1})$  is necessarily autocorrelated with correlation  $-0.5$ . Therefore, we should not use a weight matrix that assumes the errors are independent. For dynamic panel-data models, we can show that the appropriate initial weight matrix is

$$\widehat{\mathbf{W}} = \left( \frac{1}{N} \sum_i \mathbf{Z}_i' \mathbf{H}_D \mathbf{Z}_i \right)^{-1}$$

where

$$\mathbf{H}_D = \begin{bmatrix} 1 & -0.5 & 0 & \dots & 0 & 0 \\ -0.5 & 1 & -0.5 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 1 & -0.5 \\ 0 & 0 & 0 & \dots & -0.5 & 1 \end{bmatrix}$$

We can obtain this initial weight matrix by specifying `winitial(xt D)`. The letter D indicates that the equation we are estimating is specified in first differences.

## ▶ Example 17: Arellano–Bond estimator

Say we want to fit the model

$$\mathbf{n}_{it} = \rho \mathbf{n}_{i,t-1} + \beta_1 \mathbf{w}_{it} + \beta_2 \mathbf{w}_{i,t-1} + \beta_3 \mathbf{k}_{it} + \beta_4 \mathbf{k}_{i,t-1} + u_i + \epsilon_{it} \quad (19)$$

where we assume that  $\mathbf{w}_{it}$  and  $\mathbf{k}_{it}$  are strictly exogenous. First-differencing, our residual equation is

$$\begin{aligned} \epsilon_{it}^* = (\epsilon_{it} - \epsilon_{i,t-1}) = & \mathbf{n}_{it} - \mathbf{n}_{i,t-1} - \rho (\mathbf{n}_{i,t-1} - \mathbf{n}_{i,t-2}) - \beta_1 (\mathbf{w}_{it} - \mathbf{w}_{i,t-1}) \\ & - \beta_2 (\mathbf{w}_{i,t-1} - \mathbf{w}_{i,t-2}) - \beta_3 (\mathbf{k}_{it} - \mathbf{k}_{i,t-1}) - \beta_4 (\mathbf{k}_{i,t-1} - \mathbf{k}_{i,t-2}) \end{aligned} \quad (20)$$

In Stata, we type

```
Instruments for equation 1:
XT-style: L(2/.).n
Standard: D.w LD.w D.k LD.k
```

Because  $\mathbf{w}$  and  $\mathbf{k}$  are strictly exogenous, we specified their variants that appear in (20) in the `instruments()` option; because there is no constant term in the model, we specified `noconstant` to omit the constant from the instrument list.

We specified `xtinstruments(n, lags(2/.))` to tell `gmm` what instruments to use for the lagged dependent variable included as a regressor in (19). On the basis of our previous discussion, lags two and higher of  $\mathbf{n}_{it}$  can serve as instruments. The `lags(2/.)` suboption tells `gmm` that the first available instrument for  $\mathbf{n}_{it}$  is the lag-two value  $\mathbf{n}_{i,t-2}$ . The “.” tells `gmm` to use all further lags of  $\mathbf{n}_{it}$  as instruments as well. The instrument matrices in dynamic panel-data models can become large if the dataset has many time periods per panel. In those cases, you could specify, for example, `lags(2/4)` to use just lags two through four instead of using all available lags.

Our results are identical to those we would obtain using `xtabond` with the syntax

```
xtabond n L(0/1) .w L(0/1) .k, lags(1) noconstant vce(robust)
```

If we had left off the `vce(robust)` option in our call to `xtabond`, we would have had to specify `vce(unadjusted)` in our call to `gmm` to obtain the same standard errors.

◀

### □ Technical note

`gmm` automatically excludes observations for which there are no valid observations for the panel-style instruments. However, it keeps in the estimation sample those observations for which fewer than the maximum number of instruments you requested are available. For example, if you specify the `lags(2/4)` suboption, you have requested three instruments, but `gmm` will keep observations even if only one or two instruments are available.

□

### ▷ Example 18: Two-step Arellano–Bond estimator

Here we refit the model from [example 17](#), using the two-step GMM estimator.

```
. gmm (D.n - {rho}*LD.n - {xb:D.w LD.w D.k LD.k}),
> xt instruments(n, lags(2/.)) instruments(D.w LD.w D.k LD.k, noconstant)
> deriv(/rho = -1*LD.n) deriv(/xb = -1) winitial(xt D) wmatrix(robust)
> vce(unadjusted)
```

Step 1:

Iteration 0: GMM criterion Q(b) = .0011455

Iteration 1: GMM criterion Q(b) = .00009103

Iteration 2: GMM criterion Q(b) = .00009103

Step 2:

Iteration 0: GMM criterion Q(b) = .44107941

Iteration 1: GMM criterion Q(b) = .4236729

Iteration 2: GMM criterion Q(b) = .4236729 (backed up)

Our results match those you would obtain with the command

```
xtabond n L(0/1) . (w k) , lags(1) noconstant twostep
```

## □ Technical note

If we had specified `vce(robust)` in our call to `gmm`, we would have obtained the traditional sandwich-based robust covariance matrix, but our standard errors would not match those we would obtain by specifying `vce(robust)` with the `xtabond` command. The `xtabond`, `xtdpd`, and `xtdpdsys` commands implement a bias-corrected robust VCE for the two-step GMM dynamic panel-data estimator. Traditional VCEs computed after the two-step dynamic panel-data estimator have been shown to exhibit often-severe bias; see [Windmeijer \(2005\)](#).

Neither of the two dynamic panel-data examples (17 and 18) we have fit so far include a constant term. When a constant term is included, the dynamic panel-data estimator is in fact a two-equation system estimator. For notational simplicity, consider a simple model containing just a constant term and one lag of the dependent variable:

$$y_{it} = \alpha + \rho y_{i,t-1} + u_i + \epsilon_{it}$$

First-differencing to remove the  $u_i$  term, we have

$$y_{it} - y_{i,t-1} = \rho(y_{i,t-1} - y_{i,t-2}) + (\epsilon_{it} - \epsilon_{i,t-1}) \quad (21)$$

This has also eliminated the constant term. If we assume  $E(u_i) = 0$ , which is reasonable if a constant term is included in the model, then we can recover  $\alpha$  by including the moment condition

$$y_{it} = \alpha + \rho y_{i,t-1} + \epsilon'_{it} \quad (22)$$

where  $\epsilon'_{it} = u_i + \epsilon_{it}$ . The parameter  $\rho$  continues to be identified by (21), so the only instrument we use with (22) is a constant term. As before, the error term  $(\epsilon_{i,t} - \epsilon_{i,t-1})$  is necessarily autocorrelated with correlation coefficient  $-0.5$ , though the error term  $\epsilon'_{it}$  is white noise. Therefore, our initial weight matrix should be

$$\widehat{\mathbf{W}} = \left( \frac{1}{N} \sum_i \mathbf{z}'_i \mathbf{H} \mathbf{z}_i \right)^{-1}$$

where

$$\mathbf{H} = \begin{bmatrix} \mathbf{H}_D & \mathbf{0} \\ \mathbf{0} & \mathbf{I} \end{bmatrix}$$

and  $\mathbf{I}$  is a conformable identity matrix.

One complication arises concerning the relevant estimation sample. Looking at (21), we apparently lose the first two observations from each panel because of the presence of  $y_{i,t-2}$ , but in (22), we need to sacrifice only one observation for  $y_{i,t-1}$ . For most multiple-equation models, we need to use the same estimation sample for all equations. However, in dynamic panel-data models, we can use more observations to fit the equation in level form [(22) here] than the equation in first differences [equation (21)]. To request this behavior, we specify the `nocommonesample` option to `gmm`. That option tells `gmm` to use as many observations as possible for each equation, ignoring the loss of observations due to lagging or differencing.

## ▷ Example 19: Arellano–Bond estimator with constant term

Here we fit the model

$$\mathbf{n}_{it} = \alpha + \rho \mathbf{n}_{i,t-1} + u_i + \epsilon_{it}$$

Without specifying derivatives, our command would be

```
. gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
> xtinstruments(1: n, lags(2/.)) instruments(1:, noconstant) onestep
> winitial(xt DL) vce(unadj) nocommonesample
```

We would specify `winitial(xt DL)` to obtain the required initial weight matrix. The notation `DL` indicates that our first residual equation is in first differences and that the second residual equation is in levels (not first-differenced). We exclude a constant in the instrument list for the first equation because first-differencing removed the constant term. Because we do not specify the `instruments()` option for the second residual equation, a constant is used by default.

This example also provides us the opportunity to illustrate how to specify derivatives for multiple-equation GMM models. Within the `derivative()` option, instead of specifying just the parameter name, now you must specify the equation name or number, a slash, and the parameter name to which the derivative applies. In Stata, we type

```
. gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
> xtinstruments(1: n, lags(2/.)) instruments(1:, noconstant)
> derivative(1/rho = -1*LD.n) derivative(2/alpha = -1)
> derivative(2/rho = -1*L.n) winitial(xt DL) vce(unadj) nocommonesample onestep
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = .09894466
Iteration 1: GMM criterion Q(b) = .00023508
Iteration 2: GMM criterion Q(b) = .00023508
```

GMM estimation

Number of parameters = 2

Number of moments = 29

Initial weight matrix: XT DL Number of obs = \*

|        | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|--------|-------------|-----------|-------|-------|----------------------|----------|
| /rho   | 1.023349    | .0608293  | 16.82 | 0.000 | .9041259             | 1.142572 |
| /alpha | -.0690864   | .0660343  | -1.05 | 0.295 | -.1985112            | .0603384 |

\* Number of observations for equation 1: 751

Number of observations for equation 2: 891

Instruments for equation 1:

XT-style: L(2/.).n

Instruments for equation 2:

Standard: \_cons

These results are identical to those we would obtain by typing

```
xtabond n, lags(1)
```

Because we specified `nocommonesample`, `gmm` did not report the number of observations used in the header of the output. In this dataset, there are in fact 1,031 observations on 140 panels. In the second equation, the presence of the lagged value of `n` reduces the sample size for that equation to  $1031 - 140 = 891$ . In the first equation, we lose the first two observations per panel because of lagging and differencing, which leads to 751 usable observations. These tallies are listed after the coefficient table in the output.

## □ Technical note

## Specifying

```
xtinstruments(x1 x2 x3, lags(1/3))
```

differs from

```
instruments(L(1/3).(x1 x2 x3))
```

in how observations are excluded from the estimation sample. When you use the latter syntax, `gmm` must exclude the first three observations from each panel when computing the residual equation: you requested that three lags of each regressor be used as instruments, so the first residual that could be interacted with those instruments is the one for  $t = 4$ . On the other hand, when you use `xtinstruments()`, you are telling `gmm` that you would like to use up to the first three lags of `x1`, `x2`, and `x3` as instruments but that using just one lag is acceptable. Because most panel datasets have a relatively modest number of observations per panel, dynamic instrument lists are typically used so that the number of usable observations is maximized. Dynamic instrument lists also accommodate the fact that there are more valid instruments for later time periods than earlier time periods.

Specifying panel-style instruments using the `xtinstruments()` option also affects how the standard instruments specified in the `instruments()` option are treated. To illustrate, we will suppose that we have a balanced panel dataset with  $T = 5$  observations per panel and that we specify

```
. gmm ..., xtinstruments(w, lags(1/2)) instruments(x)
```

We will lose the first observation because we need at least one lag of `w` to serve as an instrument. Our instrument matrix for panel  $i$  will therefore be

$$\mathbf{Z}_i = \begin{bmatrix} w_{i1} & 0 & 0 & 0 \\ 0 & w_{i1} & 0 & 0 \\ 0 & w_{i2} & 0 & 0 \\ 0 & 0 & w_{i2} & 0 \\ 0 & 0 & w_{i3} & 0 \\ 0 & 0 & 0 & w_{i3} \\ 0 & 0 & 0 & w_{i4} \\ x_{i2} & x_{i3} & x_{i4} & x_{i5} \\ 1 & 1 & 1 & 1 \end{bmatrix} \quad (23)$$

The vector of ones in the final row represents the constant term implied by the `instruments()` option. Because we lost the first observation, the residual vector  $\mathbf{u}_i$  will be  $4 \times 1$ . Thus, our moment conditions for the  $i$ th panel can be written in matrix notation as

$$E\{\mathbf{Z}_i \mathbf{u}_i(\boldsymbol{\beta})\} = E\left\{\mathbf{Z}_i \begin{bmatrix} u_{i2}(\boldsymbol{\beta}) \\ u_{i3}(\boldsymbol{\beta}) \\ u_{i4}(\boldsymbol{\beta}) \\ u_{i5}(\boldsymbol{\beta}) \end{bmatrix}\right\} = \mathbf{0}$$

The moment conditions corresponding to the final two rows of (23) say that

$$E\left\{\sum_{t=2}^{T-4} x_{it} u_{it}(\boldsymbol{\beta})\right\} = 0 \quad \text{and} \quad E\left\{\sum_{t=2}^{T-4} u_{it}(\boldsymbol{\beta})\right\} = 0$$

Because we specified panel-style instruments with the `xtinstruments()` option, `gmm` no longer uses moment conditions for strictly exogenous variables of the form  $E\{x_{it}u_{it}(\beta)\} = 0$  for each  $t$ . Instead, the moment conditions now stipulate that the average (over  $t$ ) of  $x_{it}u_{it}(\beta)$  has expectation zero. This corresponds to the approach proposed by [Arellano and Bond \(1991, 280\)](#) and others.

When you request panel-style instruments with the `xtinstruments()` option, the number of instruments in the  $Z_i$  matrix increases quadratically in the number of periods. The dynamic panel-data estimators we have discussed in this section are designed for datasets that contain a large number of panels and a modest number of time periods. When the number of time periods is large, estimators that use standard (non-panel-style) instruments are more appropriate. □

We have focused on the Arellano–Bond dynamic panel-data estimator because of its relative simplicity. `gmm` can additionally fit any models that can be formulated using the `xtdpd` and `xtdpdsys` commands; see [\[XT\] xtdpd](#) and [\[XT\] xtdpdsys](#). The key is to determine the appropriate instruments to use for the level and difference equations. You may find it useful to fit a version of your model with those commands to determine what instruments and XT-style instruments to use. We conclude this section with an example using the Arellano–Bover/Blundell–Bond estimator.

### ▷ Example 20: Arellano–Bover/Blundell–Bond estimator

We fit a small model that includes one lag of the dependent variable `n` as a regressor as well as the contemporaneous and first lag of `w`, which we assume are strictly exogenous. When we apply virtually all the syntax issues we have discussed so far, the `gmm` command is

```
. gmm (n - {rho}*L.n - {w}*w - {lagw}*L.w - {c})
> (D.n - {rho}*LD.n - {w}*D.w - {lagw}*LD.w),
> xtinst(1: D.n, lags(1/1)) xtinst(2: n, lags(2/.))
> inst(2: D.w LD.w, noconstant)
> deriv(1/rho = -1*L.n) deriv(1/w = -1*w)
> deriv(1/lagw = -1*L.w) deriv(1/c = -1)
> deriv(2/rho = -1*LD.n) deriv(2/w = -1*D.w)
> deriv(2/lagw = -1*LD.w)
> winit(xt LD) wmatrix(robust) vce(unadjusted) nocommonesample
```

Step 1:

```
Iteration 0: GMM criterion Q(b) = .10170339
Iteration 1: GMM criterion Q(b) = .00022772
Iteration 2: GMM criterion Q(b) = .00022772
```

Step 2:

```
Iteration 0: GMM criterion Q(b) = .59965014
Iteration 1: GMM criterion Q(b) = .56578186
Iteration 2: GMM criterion Q(b) = .56578186
```

GMM estimation

Number of parameters = 4

Number of moments = 39

Alternatively, we could have fit this model with `xtdpdsys` by typing the following:

```
xtdpdsys n L(0/1).w, lags(1) twostep
```

◀

## Details of moment-evaluator programs

In examples 11, 12, 13, and 14, we used moment-evaluator programs to evaluate moment conditions that could not be specified using the interactive version of `gmm`. In example 13, we also showed how to pass additional information to an evaluator program. Here we discuss how to make moment-evaluator programs provide derivatives and accept weights.

The complete specification for a moment-evaluator program's syntax statement is

```
syntax varlist if [weight], at(name) options [derivatives(varlist)]
```

The macro 'varlist' contains the list of variables that we are to fill in with the values of our residual equations. The macro 'if' represents an if condition that restricts the estimation sample. The macro 'at' represents a vector containing the parameter values at which we are to evaluate our residual equations. options represent other options that you specify in your call to `gmm` and want to have passed to your moment-evaluator programs. In example 13, we included the `mylhs()` option so that we could pass the name of the dependent variable to our evaluator program.

Two new elements of the syntax statement allow for weights and derivatives. `weight` specifies the types of weights your program allows. The interactive version of `gmm` allows for `fweights`, `awweights`, and `pweights`. However, unless you explicitly allow your moment evaluator program to accept weights, you cannot specify weights in your call to `gmm` with the moment-evaluator program version.

The `derivatives()` option is used to pass to your program a set of variables that you are to fill in with the derivatives of your residual equations with respect to the parameters.

To indicate that your program can calculate derivatives, you specify either the `hasderivatives` or the `haslfdderivatives` option to `gmm`. The `hasderivatives` option indicates that your program calculates parameter-level derivatives; that method requires more work but can be applied to any GMM

problem. The `haslfdderivatives` option requires less work but can be used only when the model's residual equations satisfy certain restrictions and when you use the `{lname:varlist}` syntax with the `parameters()` option.

We first consider how to write the derivative computation logic to work with the `hasderivatives` option and provide an example; then, we do the same for the `haslfdderivatives` option.

Say that you specify  $k$  parameters in the `nparameters()` or `parameters()` option and  $q$  equations in the `nequations()` or `equations()` option and that you specify `hasderivatives`. Then, `'derivatives'` will contain  $k \times q$  variables. The first  $k$  variables are for the derivatives of the first residual equation with respect to the  $k$  parameters, the second  $k$  variables are for the derivatives of the second residual equation, and so on.

### ▷ Example 21: Specifying derivatives with simple parameter names

To focus on how to specify derivatives, we return to the simple moment-evaluator program we used in [example 11](#), in which we had three regressors, and extend it to supply derivatives. The residual equation corresponding to moment condition (9) is

$$u_{it}(\beta) = y_{it} - \mu_{it} \frac{\bar{y}_i}{\bar{\mu}_i}$$

where  $\mu_{it}$ ,  $\bar{\mu}_i$ , and  $\bar{y}_i$  were defined previously. Now,

$$\frac{\partial}{\partial \beta_j} u_{it}(\beta) = -\mu_{it} \frac{\bar{y}_i}{\bar{\mu}_i^2} \left( x_{it}^{(j)} \bar{\mu}_i - \frac{1}{T} \sum_{l=1}^T x_{il}^{(j)} \mu_{il} \right) \quad (24)$$

where  $x_{it}^{(j)}$  represents the  $j$ th element of  $\mathbf{x}_{it}$ .

Our moment-evaluator program is

```

program gmm_poideriv
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name) [derivatives(varlist)]
 quietly {
 // Calculate residuals as before
 tempvar mu mubar ybar
 generate double 'mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] //
 + x3*'at'[1,3]) 'if'
 egen double 'mubar' = mean('mu') 'if', by(id)
 egen double 'ybar' = mean(y) 'if', by(id)
 replace 'varlist' = y - 'mu'*'ybar'/'mubar' 'if'
 // Did -gmm- request derivatives?
 if "'derivatives'" == "" {
 exit // no, so we are done
 }
 // Calculate derivatives
 // We need the panel means of x1*mu, x2*mu, and x3*mu
 tempvar work x1mubar x2mubar x3mubar
 generate double 'work' = x1*'mu' 'if'
 egen double 'x1mubar' = mean('work') 'if', by(id)
 replace 'work' = x2*'mu' 'if'
 egen double 'x2mubar' = mean('work') 'if', by(id)
 }

```

```

replace 'work' = x3*'mu' 'if'
egen double 'x3mubar' = mean('work') 'if', by(id)

local d1: word 1 of 'derivatives'
local d2: word 2 of 'derivatives'
local d3: word 3 of 'derivatives'
replace 'd1' = -1*'mu'*'ybar'/'mubar'^2*(x1*'mubar' - 'x1mubar')
replace 'd2' = -1*'mu'*'ybar'/'mubar'^2*(x2*'mubar' - 'x2mubar')
replace 'd3' = -1*'mu'*'ybar'/'mubar'^2*(x3*'mubar' - 'x3mubar')
}

end

```

The `derivatives()` option is made optional in the `syntax` statement by placing it in square brackets. If `gmm` needs to evaluate your residual equations but does not need derivatives at that time, then the `derivatives()` option will be empty. In our program, we check to see whether that is the case and, if so, `exit` without calculating derivatives. As is often the case with [R] `ml` as well, the portion of our program devoted to derivatives is longer than the code to compute the objective function.

The first part of our derivative code computes the term

$$\frac{1}{T} \sum_{l=1}^{l=T} x_{il}^{(j)} \mu_{il} \quad (25)$$

for  $x_{it}^{(j)} = x_1, x_2,$  and  $x_3$ . The `'derivatives'` macro contains three variable names corresponding to the three parameters of the `'at'` matrix. We extract those names into local macros `'d1'`, `'d2'`, and `'d3'` and then fill in the variables those macros represent with the derivatives shown in (24).

With our program written, we fit our model by typing

```

. use https://www.stata-press.com/data/r19/poisson1, clear
. gmm gmm_poideriv, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives

Instruments for equation 1: x1 x2 x3

Our results are identical to those in [example 11](#). Another way to verify that our program calculates derivatives correctly would be to type

```
. gmm gmm_poideriv, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Without the `hasderivatives` or `haslfdderivatives` option, `gmm` will not request derivatives from your program, even if it contains code to compute them. If you have trouble obtaining convergence with the `hasderivatives` or `haslfdderivatives` option but do not have trouble without specifying one of them, then you need to recheck your derivatives. ◀

After [example 11](#), we remarked that the evaluator program would have to be changed to accommodate different regressors. We then showed how you can specify parameters using the syntax `{lname:varlist}` and then use `matrix score` to compute linear combinations of variables. To specify derivatives when you specify parameters using this notation, ensure that your residual equations satisfy the “linear-form restriction” analogous to the restrictions of linear-form evaluators used by `ml`. See [\[R\] ml](#) and [Pitblado, Poi, and Gould \(2024\)](#) for more information about linear-form evaluators.

A GMM residual equation satisfies the linear-form restriction if the equation can be written in terms of a single observation in the dataset and if the equation for observation  $i$  does not depend on any observations  $j \neq i$ . Cross-sectional models satisfy the linear-form restriction. Time-series models satisfy the linear-form restriction only when no lags or leads are used.

Panel-data models often do not satisfy the linear-form restriction. For example, recall moment condition (9) for a panel Poisson model. That residual equation included panel-level mean terms  $\bar{y}_i$  and  $\bar{\mu}_i$ , so the residual equation for an individual observation depends on all the observations in the same panel.

When a residual equation does not satisfy the linear-form restriction, neither will its derivatives. To apply the chain rule, we need a way to multiply the `lname`-level derivative by each of the variables in the equation to obtain parameter-level derivatives. In (24), for example, there is no way to factor out each  $x_{it}^{(j)}$  variable and obtain an `lname`-level derivative that we then multiply by each of the  $x_{it}^{(j)}$ s.

Suppose we do have a model with  $q = 2$  moment conditions, both of which do satisfy the linear-form restriction, and we specify the `parameters()` option like this:

```
. gmm ..., parameters({eq1:x1 x2 _cons} {eq2:_cons} {eq3:x1 x2 _cons})
```

We have specified  $n = 3$  `lcnames` in the `parameters()` option: `eq1`, `eq2`, and `eq3`. When we specify the `haslfdderivatives` option, `gmm` will pass  $n \times q = 3 \times 2 = 6$  variables in the `derivatives()` option. The first three variables are to be filled with

$$\frac{\partial}{\partial \text{eq1}} u_{1i}(\beta) \quad \frac{\partial}{\partial \text{eq2}} u_{1i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \text{eq3}} u_{1i}(\beta)$$

where  $u_{1i}(\beta)$  is the  $i$ th observation for the first moment equation. Then, the second three variables are to be filled with

$$\frac{\partial}{\partial \text{eq1}} u_{2i}(\beta) \quad \frac{\partial}{\partial \text{eq2}} u_{2i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \text{eq3}} u_{2i}(\beta)$$

where  $u_{2i}(\beta)$  is the second moment equation. In this example, we filled in a total of six variables with derivatives. If we instead used the `hasderivatives` option, we would have filled  $k \times q = 7 \times 2 = 14$  variables; moreover, if we wanted to change the number of variables in our model, we would have modified our evaluator program.

► Example 22: Specifying derivatives with linear-form residual equations

In examples 9 and 10, we showed how to specify derivatives with an exponential regression model when using the interactive version of `gmm`. Here we show how to write a moment-evaluator program for the exponential regression model, including derivatives.

The residual equation for observation  $i$  is

$$u_i = y_i - \exp(\mathbf{x}'_i\boldsymbol{\beta})$$

where  $\mathbf{x}_i$  may include a constant term. The derivative with respect to the linear combination  $\mathbf{x}'_i\boldsymbol{\beta}$  is

$$\frac{\partial u_i}{\partial \mathbf{x}'_i\boldsymbol{\beta}} = -\exp(\mathbf{x}'_i\boldsymbol{\beta})$$

To verify that this residual equation satisfies the linear-form restriction, we see that for the  $j$ th element of  $\boldsymbol{\beta}$ , we have

$$\frac{\partial u_i}{\partial \beta_j} = -x_{ij} \exp(\mathbf{x}'_i\boldsymbol{\beta}) = \frac{\partial u_i}{\partial \mathbf{x}'_i\boldsymbol{\beta}} \times x_{ij}$$

so that given  $\partial u_i / \partial \mathbf{x}'_i\boldsymbol{\beta}$ , `gmm` can apply the chain rule to obtain the derivatives with respect to the individual parameters.

Our moment-evaluator program is

```

program gmm_poideriv2
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if, at(name) [derivatives(varlist)]
 quietly {
 tempvar mu
 matrix score double 'mu' = 'at' 'if', eq(#1)
 replace 'mu' = exp('mu')
 local depvar : coleq 'at'
 local depvar : word 1 of 'depvar'
 replace 'varlist' = 'depvar' - 'mu' 'if'
 // Did -gmm- request derivatives?
 if "'derivatives'" == "" {
 exit // no, so we are done
 }
 // Calculate derivatives
 // The derivatives macro only has one variable
 // for this model.
 replace 'derivatives' = -1*'mu' 'if'
 }
end

```

To fit our model of doctor visits treating income as an endogenous regressor, we type

```

Instruments for equation 1: private chronic female age black hispanic \_cons

Our results match those shown in [example 10](#).

We can change the variables in our model just by changing the `parameters()` and `instruments()` options; we do not need to make any changes to the moment-evaluator program, because we used linear-form derivatives.

◀

Depending on your model, allowing your moment-evaluator program to accept weights may be as easy as modifying the syntax command to allow them, or it may require significantly more work. If your program uses only commands such as `generate` and `replace`, then just modifying the syntax command is all you need to do; `gmm` takes care of applying the weights to the observation-level residuals when computing the sample moments, derivatives, and weight matrices. On the other hand, if your moment-evaluator program computes residuals using statistics that depend on multiple observations, then you must apply the weights passed to your program when computing those statistics.

In our examples of panel Poisson with strictly exogenous regressors ([11](#) and [21](#)), we used the statistics  $\bar{\mu}_i$  and  $\bar{y}_i$  when computing the residuals. If we are to allow weights with our moment-evaluator program, then we must incorporate those weights when computing  $\bar{\mu}_i$  and  $\bar{y}_i$ . Moreover, looking at the derivative in [\(24\)](#), we see that the term highlighted in [\(25\)](#) is in fact a sample mean, so we must incorporate weights when computing it.

## ▶ Example 23: Panel Poisson with derivatives and weights

Here we modify the program in [example 21](#) to accept frequency weights. One complication arises: we had been using `egen` to compute  $\bar{\mu}_i$  and  $\bar{y}_i$ . `egen` does not accept weights, so we must compute  $\bar{\mu}_i$  and  $\bar{y}_i$  ourselves, incorporating any weights the user may specify. Our program is

```

program gmm_poiderivfw
 version 19.5 // (or version 19 if you do not have StataNow)
 syntax varlist if [fweight/], at(name) [derivatives(varlist)]
 quietly {
 if "'exp'" == "" { // no weights
 local exp 1 // weight each observation equally
 }

 // Calculate residuals as before
 tempvar mu mubar ybar sumwt
 generate double 'mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] ///
 + x3*'at'[1,3]) 'if'

 bysort id: generate double 'sumwt' = sum('exp')
 by id: generate double 'mubar' = sum('mu'*'exp')
 by id: generate double 'ybar' = sum(y*'exp')
 by id: replace 'mubar' = 'mubar'[_N] / 'sumwt'[_N]
 by id: replace 'ybar' = 'ybar'[_N] / 'sumwt'[_N]
 replace 'varlist' = y - 'mu'*'ybar'/'mubar' 'if'

 // Did -gmm- request derivatives?
 if "'derivatives'" == "" {
 exit // no, so we are done
 }

 // Calculate derivatives
 // We need the panel means of x1*mu, x2*mu, and x3*mu
 tempvar work x1mubar x2mubar x3mubar
 generate double 'work' = x1*'mu' 'if'
 by id: generate double 'x1mubar' = sum('work'*'exp')
 by id: replace 'x1mubar' = 'x1mubar'[_N] / 'sumwt'[_N]
 replace 'work' = x2*'mu' 'if'
 by id: generate double 'x2mubar' = sum('work'*'exp')
 by id: replace 'x2mubar' = 'x2mubar'[_N] / 'sumwt'[_N]
 replace 'work' = x3*'mu' 'if'
 by id: generate double 'x3mubar' = sum('work'*'exp')
 by id: replace 'x3mubar' = 'x3mubar'[_N] / 'sumwt'[_N]

 local d1: word 1 of 'derivatives'
 local d2: word 2 of 'derivatives'
 local d3: word 3 of 'derivatives'
 replace 'd1' = -1*'mu'*'ybar'/'mubar'^2*(x1*'mubar' - 'x1mubar')
 replace 'd2' = -1*'mu'*'ybar'/'mubar'^2*(x2*'mubar' - 'x2mubar')
 replace 'd3' = -1*'mu'*'ybar'/'mubar'^2*(x3*'mubar' - 'x3mubar')
 }
end

```

Our syntax command now indicates that `fweights` are allowed. The first part of our code looks at the macro `'exp'`. If it is empty, then the user did not specify weights in their call to `gmm`; and we set the macro equal to 1 so that we weight each observation equally. After we compute  $\mu_{it}$ , we calculate  $\bar{\mu}_i$  and  $\bar{y}_i$ , accounting for weights. To compute frequency-weighted means for each panel, we just multiply each observation by its respective weight, sum over all observations in the panel, then divide by the sum of the weights for the panel. (See [\[U\] 20.24 Weighted estimation](#) for information on how to handle `aweights` and `pweights`.) We use the same procedure to compute the frequency-weighted variant of expression (25) in the derivative calculations. To use our program, we type

```
. use https://www.stata-press.com/data/r19/poissonwts
. gmm gmm_poiderivfw [fw=fwt], nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives

Testing whether our program works correctly with frequency weights is easy. A frequency-weighted dataset is just a compact form of a larger dataset in which identical observations are omitted and a frequency-weight variable is included to tell us how many times each observation in the smaller dataset appears in the larger dataset. Therefore, we can expand our smaller dataset by the frequency-weight variable and then refit our model without specifying frequency weights. If we obtain the same results, our program works correctly. When we type

```
. expand fw
. gmm gmm_poiderivfw, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

we obtain the same results as before.

| <code>e(W)</code>            | weight matrix used for final round of estimation                               |
| <code>e(S)</code>            | moment covariance matrix used in robust VCE computations                       |
| <code>e(G)</code>            | averages of derivatives of moment conditions                                   |
| <code>e(N_byequation)</code> | number of observations per equation, if <code>nocommonesample</code> specified |
| <code>e(V)</code>            | variance–covariance matrix                                                     |
| <code>e(V_modelbased)</code> | model-based variance                                                           |

## Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|                       |                                                                                                                       |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------|
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Let  $q$  denote the number of moment conditions. For observation  $i$ ,  $i = 1, \dots, N$ , write the  $j$ th moment equation as  $\mathbf{z}_{ij}u_{ij}(\beta_j)$  for  $j = 1, \dots, q$ .  $\mathbf{z}_{ij}$  is a  $1 \times m_j$  vector, where  $m_j$  is the number of instruments specified for equation  $j$ . Let  $m = m_1 + \dots + m_q$ .

Our notation can incorporate moment conditions of the form  $h_{ij}(\mathbf{w}_{ij}; \beta_j)$  with instruments  $\mathbf{w}_{ij}$  by defining  $\mathbf{z}_{ij} = 1$  and  $u_{ij}(\beta_j) = h_{ij}(\mathbf{w}_{ij}; \beta_j)$ , so except when necessary, we do not distinguish between the two types of moment conditions. We could instead use notation so that all our moment conditions are of the form  $h_{ij}(\mathbf{w}_{ij}; \beta_j)$ , or we could adopt notation that explicitly combines both forms of moment equations. However, because moment conditions of the form  $\mathbf{z}'_{ij}u_{ij}(\beta_j)$  are arguably more common, we use that notation.

Let  $\beta$  denote a  $k \times 1$  vector of parameters, consisting of all the unique parameters of  $\beta_1, \dots, \beta_q$ . Then, we can stack the moment conditions and write them more compactly as  $\mathbf{Z}'_i \mathbf{u}_i(\beta)$ , where

$$\mathbf{Z}'_i = \begin{bmatrix} \mathbf{z}_{i1} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{z}_{i2} & \cdots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{z}_{iq} \end{bmatrix} \quad \text{and} \quad \mathbf{u}_i(\beta) = \begin{bmatrix} u_{i1}(\beta_1) \\ u_{i2}(\beta_2) \\ \vdots \\ u_{iq}(\beta_q) \end{bmatrix}$$

The GMM estimator  $\hat{\beta}$  is the value of  $\beta$  that minimizes

$$Q(\beta) = \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\}' \mathbf{W} \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\} \quad (\text{A1})$$

for  $q \times q$  weight matrix  $\mathbf{W}$ .

By default, `gmm` minimizes (A1) using the Gauss–Newton method. See Hayashi (2000, 498) for a derivation. This technique is typically faster than quasi-Newton methods and does not require second-order derivatives.

Methods and formulas are presented under the following headings:

*Initial weight matrix*  
*Weight matrix*  
*Variance–covariance matrix*  
*Hansen’s J statistic*  
*Panel-style instruments*  
*Marginal predictions with unconditional standard errors*

### Initial weight matrix

If you specify `winitial(unadjusted)`, then we create matrix  $\Lambda$  with typical submatrix

$$\Lambda_{rs} = N^{-1} \sum_{i=1}^N \mathbf{z}'_{ir} \mathbf{z}_{is}$$

for  $r = 1, \dots, q$  and  $s = 1, \dots, q$ . If you include the `independent` suboption, then we set  $\Lambda_{rs} = \mathbf{0}$  for  $r \neq s$ . The weight matrix  $\mathbf{W}$  equals  $\Lambda^{-1}$ .

If you specify `winitial(identity)`, then we set  $\mathbf{W} = \mathbf{I}_q$ .

If you specify `winitial(xt xtspec)`, then you must specify one or two items in `xtspec`, one for each equation. `gmm` allows you to specify at most two moment equations when you specify `winitial(xt xtspec)`, one in first-differences, and one in levels. We create the block-diagonal matrix  $\mathbf{H}$  with typical block  $\mathbf{H}_j$ . If the  $j$ th element of `xtspec` is “L”, then  $\mathbf{H}_j$  is the identity matrix of suitable dimension. If the  $j$ th element of `xtspec` is “D”, then

$$\mathbf{H}_j = \begin{bmatrix} 1 & -0.5 & 0 & \dots & 0 & 0 \\ -0.5 & 1 & -0.5 & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 1 & -0.5 \\ 0 & 0 & 0 & \dots & -0.5 & 1 \end{bmatrix}$$

Then,

$$\mathbf{\Lambda}_H = N_G^{-1} \sum_{g=1}^{g=N_G} \mathbf{Z}'_g \mathbf{H} \mathbf{Z}_g$$

where  $g$  indexes panels in the dataset,  $N_G$  is the number of panels,  $\mathbf{Z}_g$  is the full instrument matrix for panel  $g$ , and  $\mathbf{W} = \mathbf{\Lambda}_H^{-1}$ . See [Panel-style instruments](#) below for a discussion of how  $\mathbf{Z}_g$  is formed.

If you specify `winitial(matname)`, then we set  $\mathbf{W}$  equal to Stata matrix `matname`.

## Weight matrix

Specification of the weight matrix applies only to the two-step and iterative estimators. When you use the `onestep` option, the `wmatrix()` option is ignored.

We first evaluate (A1) using the initial weight matrix described above and then compute  $\mathbf{u}_i(\hat{\beta})$ . In all cases,  $\mathbf{W} = \mathbf{\Lambda}^{-1}$ . If you specify `wmatrix(unadjusted)`, then we create  $\mathbf{\Lambda}$  to have typical submatrix

$$\mathbf{\Lambda}_{rs} = \sigma_{rs} N^{-1} \sum_{i=1}^N \mathbf{z}'_{ir} \mathbf{z}_{is}$$

where

$$\sigma_{rs} = N^{-1} \sum_{i=1}^N u_{ir}(\hat{\beta}) u_{is}(\hat{\beta})$$

and  $r$  and  $s$  index moment equations. For all types of weight matrices, if the independent suboption is specified, then  $\mathbf{\Lambda}_{rs} = \mathbf{0}$  for  $r \neq s$ , where  $\mathbf{\Lambda}_{rs}$  measures the covariance between moment conditions for equations  $r$  and  $s$ .

If you specify `wmatrix(robust)`, then

$$\mathbf{\Lambda} = N^{-1} \sum_{i=1}^N \mathbf{z}_i \mathbf{u}_i(\hat{\beta}) \mathbf{u}'_i(\hat{\beta}) \mathbf{z}'_i$$

If you specify `wmatrix(cluster clustvar)`, then

$$\mathbf{\Lambda} = N^{-1} \sum_{c=1}^{c=N_C} \mathbf{q}_c \mathbf{q}'_c$$

where  $c$  indexes clusters,  $N_C$  is the number of clusters, and

$$\mathbf{q}_c = \sum_{i \in c_j} \mathbf{z}_i \mathbf{u}_i(\hat{\beta})$$

If you specify `wmatrix(hac kernel [#])`, then

$$\begin{aligned} \Lambda = & N^{-1} \sum_{i=1}^N \mathbf{Z}_i \mathbf{u}_i(\hat{\beta}) \mathbf{u}_i(\hat{\beta})' \mathbf{Z}_i' + \\ & N^{-1} \sum_{l=1}^{l=N-1} \sum_{i=l+1}^N K(l, \lambda) \{ \mathbf{Z}_i \mathbf{u}_i(\hat{\beta}) \mathbf{u}_{i-l}'(\hat{\beta}) \mathbf{Z}_{i-l}' + \mathbf{Z}_{i-l} \mathbf{u}_{i-l}(\hat{\beta}) \mathbf{u}_i'(\hat{\beta}) \mathbf{Z}_i' \} \end{aligned}$$

where  $\lambda = \#$  if  $\#$  is specified and  $\lambda = N - 2$  otherwise. Define  $z = l/(\lambda + 1)$ . If `kernel` is `bartlett` or `nwest`, then

$$K(l, \lambda) = \begin{cases} 1 - z & 0 \leq z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `parzen` or `gallant`, then

$$K(l, \lambda) = \begin{cases} 1 - 6z^2 + 6z^3 & 0 \leq z \leq 0.5 \\ 2(1 - z)^3 & 0.5 < z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If `kernel` is `quadraticspectral` or `andrews`, then

$$K(l, \lambda) = \begin{cases} 1 & z = 0 \\ 3\{\sin(\theta)/\theta - \cos(\theta)\}/\theta^2 & \text{otherwise} \end{cases}$$

where  $\theta = 6\pi z/5$ .

If `wmatrix(hac kernel opt)` is specified, then `gmm` uses Newey and West's (1994) automatic lag-selection algorithm, which proceeds as follows. Define  $\mathbf{h}$  to be an  $m \times 1$  vector of ones. Note that this definition of  $\mathbf{h}$  is slightly different from the one used by `ivregress`. There the element of  $\mathbf{h}$  corresponding to the constant term equals 0, effectively ignoring the effect of the constant in determining the optimal lag length. Here we include the effect of the constant term. Now, define

$$\begin{aligned} f_i &= \{ \mathbf{Z}_i' \mathbf{u}_i(\beta) \}' \mathbf{h} \\ \hat{\sigma}_j &= N^{-1} \sum_{i=j+1}^N f_i f_{i-j} \quad j = 0, \dots, \lambda^* \\ \hat{s}^{(q)} &= 2 \sum_{j=1}^{j=\lambda^*} \hat{\sigma}_j j^q \\ \hat{s}^{(0)} &= \hat{\sigma}_0 + 2 \sum_{j=1}^{j=\lambda^*} \hat{\sigma}_j \\ \hat{\gamma} &= c_\gamma \left\{ \left( \frac{\hat{s}^{(q)}}{\hat{s}^{(0)}} \right)^2 \right\}^{1/(2q+1)} \\ \lambda &= \hat{\gamma} N^{1/(2q+1)} \end{aligned}$$

where  $q$ ,  $\lambda^*$ , and  $c_\gamma$  depend on the kernel specified:

| Kernel                     | $q$ | $\lambda^*$                         | $c_\gamma$ |
|----------------------------|-----|-------------------------------------|------------|
| Bartlett/Newey–West        | 1   | $\text{int} \{ 20(T/100)^{2/9} \}$  | 1.1447     |
| Parzen/Gallant             | 2   | $\text{int} \{ 20(T/100)^{4/25} \}$ | 2.6614     |
| Quadratic spectral/Andrews | 2   | $\text{int} \{ 20(T/100)^{2/25} \}$ | 1.3221     |

Here  $\text{int}(x)$  denotes the integer obtained by truncating  $x$  toward zero. For the Bartlett and Parzen kernels, the optimal lag is  $\min\{\text{int}(\lambda), \lambda^*\}$ . For the quadratic spectral kernel, the optimal lag is  $\min\{\lambda, \lambda^*\}$ .

If `wmatrix(hac kernel opt #)` is specified, then `gmm` uses `#` instead of 20 in the definition of  $\lambda^*$  above to select the optimal lag.

## Variance–covariance matrix

If you specify `vce(unadjusted)`, then the VCE matrix is computed as

$$\text{Var}(\widehat{\beta}) = N^{-1} \{ \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\widehat{\beta}) \}^{-1} \quad (\text{A2})$$

where

$$\overline{\mathbf{G}}(\widehat{\beta}) = N^{-1} \sum_{i=1}^N \mathbf{z}'_i \left. \frac{\partial \mathbf{u}_i(\beta)}{\partial \beta'} \right|_{\beta=\widehat{\beta}} \quad (\text{A3})$$

For the two-step and iterated estimators, we use the weight matrix  $\mathbf{W}$  that was used to compute the final-round estimate  $\widehat{\beta}$ .

When you do not specify analytic derivatives, `gmm` must compute the Jacobian matrix (A3) numerically. By default, `gmm` computes each element of the matrix individually by using the Mata `deriv()` function; see [M-5] `deriv()`. This procedure results in accurate derivatives but can be slow if your model has many instruments or parameters.

When you specify the `quickderivatives` option, `gmm` computes all derivatives corresponding to parameter  $\beta_j$ ,  $j = 1, \dots, q$ , at once, using two-sided derivatives with a step size of  $|\beta_j| \epsilon^{1/3}$ , where  $\epsilon$  is the machine precision of a double precision number (approximately  $2.22045 \times 10^{-16}$ ). This method requires just two evaluations of the model's moments to compute an entire column of (A3) and therefore has the most impact when you specify many instruments or moment equations so that (A3) has many rows.

For the one-step estimator, how the unadjusted VCE is computed depends on the type of initial weight matrix requested and the form of the moment equations. If you specify two or more moment equations of the form  $h_{ij}(\mathbf{w}_{ij}; \beta_j)$ , then `gmm` issues a note and computes a heteroskedasticity-robust VCE because here the matrix  $\mathbf{Z}'\mathbf{Z}$  is necessarily singular; moreover, here you must use the identity matrix as the initial weight matrix. Otherwise, if you specify `winitial(unadjusted)` or `winitial(identity)`, then `gmm` first computes an unadjusted weight matrix based on  $\widehat{\beta}$  before evaluating (A2). If you specify `winitial(matname)`, then (A2) is evaluated on the basis of `matname`; the user is responsible for verifying that the VCE and other statistics so produced are appropriate.

All types of robust VCEs computed by `gmm` take the form

$$\text{Var}(\widehat{\beta}) = N^{-1} \{ \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\widehat{\beta}) \}^{-1} \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \mathbf{S} \overline{\mathbf{G}}(\widehat{\beta}) \{ \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \overline{\mathbf{G}}(\widehat{\beta}) \}^{-1}$$

For the one-step estimator,  $\mathbf{W}$  represents the initial weight matrix requested using the `winitial()` option, and  $\mathbf{S}$  is computed on the basis of the specification of the `vce()` option. The formulas for the  $\mathbf{S}$  matrix are identical to the ones that define the  $\mathbf{\Lambda}$  matrix in *Weight matrix* above, except that  $\mathbf{S}$  is computed after the moment equations are reevaluated using the final estimate of  $\widehat{\beta}$ . For the two-step and iterated GMM estimators, computation of  $\mathbf{W}$  is controlled by the `wmatrix()` option on the basis of the penultimate estimate of  $\widehat{\beta}$ .

For details on computation of the VCE matrix with dynamic panel-data models, see *Panel-style instruments* below.

## Hansen’s J statistic

Hansen’s (1982)  $J$  test of overidentifying restrictions is  $J = N \times Q(\widehat{\beta})$ .  $J \sim \chi^2(m - k)$ . If  $m < k$ , `gmm` issues an error message without estimating the parameters. If  $m = k$ , the model is just-identified and  $J$  is saved as missing (“.”). For the two-step and iterated GMM estimators, the  $J$  statistic is based on the last-computed weight matrix as determined by the `wmatrix()` option. For the one-step estimator, `gmm` recomputes a weight matrix as described in the second paragraph of [Variance–covariance matrix](#) above. To obtain Hansen’s  $J$  statistic, you use `estat overid`; see [\[R\] gmm postestimation](#).

## Panel-style instruments

Here we discuss several issues that arise only when you specify panel-style instruments by using the `xtinstruments()` option. When you specify the `xtinstruments()` option, we can no longer consider the instruments for one observation in isolation; instead, we must consider the instrument matrix for an entire panel at once. In the following discussion, we let  $T$  denote the number of time periods in a panel. To accommodate unbalanced datasets, conceptually we simply use zeros as instruments and residuals for time periods that are missing in a panel.

We consider the case where you specify both an equation in levels and an equation in differences, yielding two residual equations. Let  $u_{pt}^L(\beta)$  denote the residual for the level equation for panel  $p$  in period  $t$ , and let  $u_{pt}^D(\beta)$  denote the residual for the corresponding difference equation. Now, define the  $(2T - 1) \times 1$  vector  $\mathbf{u}_p(\beta)$  as

$$\mathbf{u}_p(\beta) = [u_{p1}^L(\beta), u_{p2}^L(\beta), \dots, u_{pT}^L(\beta), u_{p2}^D(\beta), u_{p3}^D(\beta), \dots, u_{pT}^D(\beta)]$$

The  $T + 1$  element of  $\mathbf{u}_p$  is  $u_{p2}^D(\beta)$  because we lose the first observation of the difference equation because of differencing.

We write the moment conditions for the  $p$ th panel as  $\mathbf{Z}_p \mathbf{u}_p(\beta)$ . To see how  $\mathbf{Z}_p$  is defined, we will let  $\mathbf{w}_{pt}^L$  and  $\mathbf{w}_{pt}^D$  denote the vectors of panel-style instruments for the level and difference equations, respectively, and let time be denoted by  $t$ ; we discuss their dimensions momentarily. Also let  $\mathbf{x}_{pt}^L$  and  $\mathbf{x}_{pt}^D$  denote the vectors of instruments specified in `instruments()` for the level and difference equations at time  $t$ . Without loss of generality, for our discussion, we assume that you specify the level equation first. Then,  $\mathbf{Z}_p$  has the form

$$\mathbf{Z}_p = \begin{bmatrix} \mathbf{w}_1^L & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{w}_2^L & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{w}_T^L & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{x}_1^L & \mathbf{x}_2^L & \dots & \mathbf{x}_T^L & \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{w}_1^D & \mathbf{0} & \dots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{w}_2^D & \dots & \mathbf{0} \\ \vdots & \vdots & \ddots & \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{0} & \mathbf{0} & \dots & \mathbf{w}_T^D \\ \mathbf{0} & \mathbf{0} & \dots & \mathbf{0} & \mathbf{x}_1^D & \mathbf{x}_2^D & \dots & \mathbf{x}_T^D \end{bmatrix} \tag{A4}$$

To see how the  $\mathbf{w}$  vectors are formed, we will suppose you specify

```
xtinstruments(1: d, lags(a/b))
```

Then,  $\mathbf{w}_t^L$  will be a  $(b - a + 1) \times 1$  vector consisting of  $d_{t-a}, \dots, d_{t-b}$ . If  $(t - a) \leq 0$ , then instead, we set  $\mathbf{w}_t^L = 0$ . If  $(t - a) > 0$  but  $(t - b) \leq 0$ , then we create  $\mathbf{w}_t^L$  to consist of  $d_{t-a}, \dots, d_1$ . With this definition,  $(b - a + 1)$  defines the maximum number of lags of  $d$  used, but `gmm` will proceed with fewer lags if all  $(b - a + 1)$  lags are not available. If you specify two panel-style instruments, `d` and `e`, say, then  $\mathbf{w}_t^L$  will consist of  $d_{t-a}, \dots, d_{t-b}, e_{t-a}, \dots, e_{t-b}$ .  $\mathbf{w}_t^D$  is handled analogously.

The  $\mathbf{x}_t^L$  vectors are simply  $j \times 1$  vectors, where  $j$  is the number of regular instruments specified with the `instruments()` option; these vectors include a “1” unless you specify the `noconstant` suboption.

Looking carefully at (A4), you will notice that for dynamic panel-data models, moment conditions corresponding to the instruments  $\mathbf{x}_{pt}^L$  take the form

$$E \left[ \sum_{t=1}^{t=T} \mathbf{x}_{pt}^L u_{pt}^L(\beta) \right] = \mathbf{0}$$

and likewise for  $\mathbf{x}_{pt}^D$ . Instead of having separate moment conditions for each time period, there is one moment condition equal to the average of individual periods’ moments. See [Arellano and Bond \(1991, 280\)](#). To include separate moment conditions for each time period, instead of specifying, say,

```
instruments(1: x)
```

you could instead first generate a variable called `one` equal to unity for all observations and specify

```
xtinstruments(1: x one)
```

(Creating the variable `one` is necessary because a constant is not automatically included in variable lists specified in `xtinstruments()`.)

Unbalanced panels are essentially handled by including zeros in rows and columns of  $\mathbf{Z}_p$  and  $\mathbf{u}_p(\beta)$  corresponding to missing time periods. However, the numbers of instruments and moment conditions reported by `gmm` do not reflect this trickery and instead reflect the numbers of instruments and moment conditions that are not manipulated in this way. Moreover, `gmm` includes code to work through these situations efficiently without actually having to fill in zeros.

When you specify `winitial(xt ...)`, the one-step unadjusted VCE is computed as

$$\text{Var}(\widehat{\beta}) = \widehat{\sigma}_1^2 \Lambda_H$$

where  $\Lambda_H$  is as defined previously,

$$\widehat{\sigma}_1^2 = (N - k)^{-1} \sum_{p=1}^{p=P} \mathbf{u}_p^D(\widehat{\beta})' \mathbf{u}_p^D(\widehat{\beta})$$

and  $\mathbf{u}_p^D(\widehat{\beta}) = [u_{p2}^D(\widehat{\beta}), \dots, u_{pT}^D(\widehat{\beta})]$ . Here we use  $(N - k)^{-1}$  instead of  $N^{-1}$  to match `xtdpd`.

## Marginal predictions with unconditional standard errors

Here we describe how `margins` computes unconditional standard errors when used with the `vce(unconditional)` option after `gmm`. These standard errors account for the estimation of parameters in `gmm` before `margins` is used to make marginal predictions. They also account for variation in the covariates over the population.

margins with the vce(unconditional) option uses linearization to estimate the unconditional variance of  $\widehat{\beta}$ . Linearization uses the variance estimator for the total of a score variable for the marginal prediction  $p(\widehat{\beta})$  as an approximate estimator for  $\text{Var}\{p(\widehat{\beta})\}$ . See [SVY] **Variance estimation** for more details. Our derivation of the standard errors here is similar to the derivation of the standard errors for two-step  $M$  estimators. See Wooldridge (2010, sec. 12.4) for the latter.

Let  $\mathbf{x}_i$  be a vector of covariate values, which includes all variables used in calculating the moment conditions, and let  $f(\mathbf{x}_i, \beta)$  be a scalar-valued function returning the value of the predictions of interest.

Let  $\delta_i(S_p)$  indicate whether observation  $i$  is in the subpopulation of interest,  $S_p$ ,

$$\delta_i(S_p) = \begin{cases} 1, & i \in S_p \\ 0, & i \notin S_p \end{cases}$$

margins computes  $\widehat{\theta} = p(\widehat{\beta})$  via

$$\widehat{\theta} = \frac{1}{w} \sum_{i=1}^N \delta_i(S_p) w_i f(\mathbf{x}_i, \widehat{\beta})$$

where

$$w = \sum_{i=1}^N \delta_i(S_p) w_i$$

and  $w_i$  is the weight for the  $i$ th observation.

In minimizing (A1), we see that the GMM estimator  $\widehat{\beta}$  is the value of  $\beta$  that solves the score equations

$$\mathbf{0} = \overline{\mathbf{G}}(\beta)' \mathbf{W} \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\}$$

where  $\overline{\mathbf{G}}(\beta)$  was defined in (A3).

By the mean-value theorem, for some points  $\beta_1, \dots, \beta_q$  between  $\beta$  and  $\widehat{\beta}$ , we have

$$\mathbf{0} = \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \left[ \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\} + \overline{\mathbf{G}}_m(\widehat{\beta} - \beta) \right]$$

where

$$\overline{\mathbf{G}}_{m(j,l)} = N^{-1} \sum_{i=1}^N \left[ \frac{\partial \{ \mathbf{Z}'_i \mathbf{u}_i(\beta_j) \}_l}{\partial \beta'_j} \right]_{j,l}$$

So we have

$$\sqrt{N}(\widehat{\beta} - \beta) = - \{ \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \overline{\mathbf{G}}_m \}^{-1} \overline{\mathbf{G}}(\widehat{\beta})' \mathbf{W} \left\{ N^{-0.5} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\} \quad (\text{A5})$$

The margin  $\widehat{\theta}$  is the solution to the score equations

$$\frac{1}{N} \sum_{i=1}^N s_i(\theta, \widehat{\beta}) = \mathbf{0}$$

where

$$s_i(\theta, \beta) = w_i \delta_i(S_p) \{f(\mathbf{x}_i, \beta) - \theta\}$$

When we do a mean-value expansion about point  $\theta_1$  between  $\theta$  and  $\hat{\theta}$ , we get

$$\mathbf{0} = \frac{1}{N} \sum_{i=1}^N s_i(\theta, \hat{\beta}) - w.(\hat{\theta} - \theta)$$

So we have

$$\sqrt{N}(\hat{\theta} - \theta) = w.^{-1} N^{-0.5} \sum_{i=1}^N s_i(\theta, \hat{\beta})$$

Using the mean-value theorem again, for point  $\beta_m$  between  $\beta$  and  $\hat{\beta}$ , we have

$$w.^{-1} N^{-0.5} \sum_{i=1}^N s_i(\theta, \hat{\beta}) = w.^{-1} \left\{ N^{-0.5} \sum_{i=1}^N s_i(\theta, \beta) + \sqrt{N} \bar{\mathbf{J}}(\beta_m) (\hat{\beta} - \beta) \right\}$$

where  $\bar{\mathbf{J}}(\beta_m)$  is the Jacobian of the margin at  $\beta_m$ ,

$$\bar{\mathbf{J}}(\beta_m) = \left\{ N^{-1} \sum_{i=1}^N w_i \delta_i(S_p) \frac{\partial f(\mathbf{x}_i, \beta_m)}{\partial \beta'_m} \right\}$$

Using (A5), we get

$$\sqrt{N}(\hat{\theta} - \theta) = w.^{-1} N^{-0.5} \left[ \sum_{i=1}^N s_i(\theta, \beta) - \bar{\mathbf{J}}(\beta_m) \{ \bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \bar{\mathbf{G}}_m \}^{-1} \bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \left\{ \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\beta) \right\} \right]$$

$\hat{\theta}$  is asymptotically normal, and a consistent estimator of its variance is given by

$$\widehat{\text{Var}}\{\sqrt{N}(\hat{\theta} - \theta)\} = \sum_{i=1}^N w.^{-2} \left[ s_i(\hat{\theta}, \hat{\beta}) - \bar{\mathbf{J}}(\hat{\beta}) \{ \bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \bar{\mathbf{G}}(\hat{\beta}) \}^{-1} \bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \mathbf{Z}'_i \mathbf{u}_i(\hat{\beta}) \right]^2$$

See Wooldridge (2010, sec 12.4 and 12.5) for details.

`gmm` returns  $N^{-1} \{ \bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \bar{\mathbf{G}}(\hat{\beta}) \}^{-1}$  as the model-based variance. The scores are  $-\bar{\mathbf{G}}(\hat{\beta})' \mathbf{W} \mathbf{Z}'_i \mathbf{u}_i(\hat{\beta})$  and may be predicted in postestimation; see [R] [gmm postestimation](#). These scores correspond to derivatives of the criterion function  $Q(\beta)$ , scaled by  $-1/2$ . See Cameron and Trivedi (2005, sec. 6.3.2) for more details.

`margins` estimates the asymptotic standard error of  $\hat{\theta}$  from the model-based variance, the scores, and its own predictions of  $s_i$  and the Jacobian  $\bar{\mathbf{J}}(\hat{\beta})$ .

## Postestimation commands

The following postestimation command is of special interest after `gmm`:

| Command                   | Description                                  |
|---------------------------|----------------------------------------------|
| <code>estat overid</code> | perform test of overidentifying restrictions |

The following standard postestimation commands are also available:

| Command                  | Description                                                                                       |
|--------------------------|---------------------------------------------------------------------------------------------------|
| <code>contrast</code>    | contrasts and ANOVA-style joint tests of parameters                                               |
| <code>estat vce</code>   | variance–covariance matrix of the estimators (VCE)                                                |
| <code>estimates</code>   | cataloging estimation results                                                                     |
| <code>etable</code>      | table of estimation results                                                                       |
| <code>hausman</code>     | Hausman’s specification test                                                                      |
| <code>lincom</code>      | point estimates, standard errors, testing, and inference for linear combinations of parameters    |
| <code>margins</code>     | marginal means, predictive margins, marginal effects, and average marginal effects                |
| <code>marginsplot</code> | graph the results from margins (profile plots, interaction plots, etc.)                           |
| <code>nlcom</code>       | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters |
| <code>predict</code>     | residuals                                                                                         |
| <code>predictnl</code>   | point estimates, standard errors, testing, and inference for generalized predictions              |
| <code>pwcompare</code>   | pairwise comparisons of parameters                                                                |
| <code>test</code>        | Wald tests of simple and composite linear hypotheses                                              |
| <code>testnl</code>      | Wald tests of nonlinear hypotheses                                                                |

## predict

### Description for predict

`predict` creates a new variable containing predictions such as linear predictions, residuals, and scores.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

```
predict [type] newvar [if] [in] [, xb equation(eqno | eqname)]
```

```
predict [type] newvar [if] [in], residuals [equation(eqno | eqname)]
```

```
predict [type] { stub* | newvar1 ... newvarq } [if] [in] [, residuals]
```

```
predict [type] stub* [if] [in], scores
```

Residuals are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Scores are available only for observations within the estimation sample.

You specify one new variable and (optionally) `equation()`, or you specify `stub*` or  $q$  or  $p$  new variables, where  $q$  is the number of moment equations and  $p$  is the number of parameters in the model.

### Option for predict

Main

`xb`, the default, calculates the linear prediction.

`residuals` calculates the residuals, the predicted values of the moment equations. This option requires that the length of the new variable list be equal to the number of moment equations,  $q$ . Otherwise, use `stub*` to have `predict` generate enumerated variables with prefix `stub`. If `equation()` is not specified, the  $j$ th new variable will contain the residuals for the  $j$ th moment equation.

`equation(eqno | eqname)` with `xb` refers to a linear prediction in the model, whereas `equation(eqno | eqname)` with `residuals` refers to a moment equation.

For `xb`, specifying `equation(#1)` indicates that the calculation is to be made for the first linear prediction within curly braces. Specifying `equation(xb1)` would indicate that the calculation is to be made for the linear prediction `xb1`, assuming there is a linear prediction named `xb1` in the model, for instance, `{xb1:varlist}`.

For residuals, specifying `equation(#1)` indicates that the calculation is to be made for the first moment equation. Specifying `equation(demand)` would indicate that the calculation is to be made for the moment equation named `demand`, assuming there is a moment equation named `demand` in the model.

If you specify one new variable name and omit `equation()`, results are the same as if you had specified `equation(#1)`.

For more information on using `predict` after multiple-equation estimation commands, see [R] [predict](#).

`scores` calculates the parameter-level score equations, the first derivatives of the GMM criterion function with respect to the parameters scaled by  $-0.5$ . This option requires that the length of the new variable list be equal to the number of parameters,  $p$ . Otherwise, use `stub*` to have `predict` generate enumerated variables with prefix `stub`. The  $j$ th new variable will contain the  $j$ th score of the model.

## margins

### Description for margins

`margins` estimates margins of response for linear predictions.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>       | Description                           |
|------------------------|---------------------------------------|
| <code>xb</code>        | linear prediction; the default        |
| <code>residuals</code> | not allowed with <code>margins</code> |

`xb` defaults to the first equation.

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## estat

### Description for estat

`estat overid` reports Hansen's  $J$  statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. If the model is correctly specified in the sense that  $E\{\mathbf{z}_i u_i(\boldsymbol{\beta})\} = \mathbf{0}$ , then the sample analog to that condition should hold at the estimated value of  $\boldsymbol{\beta}$ . Hansen's  $J$  statistic is valid only if the weight matrix is optimal, meaning that it equals the inverse of the covariance matrix of the moment conditions. Therefore, `estat overid` only reports Hansen's  $J$  statistic after two-step or iterated estimation, or if you specified `winitial(matname)` when calling `gmm`. In the latter case, it is your responsibility to determine the validity of the  $J$  statistic.

### Menu for estat

Statistics > Postestimation

### Syntax for estat

```
estat overid
```

`collect` is allowed with `estat overid`; see [\[U\] 11.1.10 Prefix commands](#).

### Remarks and examples

As we noted in [Introduction](#) of [\[R\] gmm](#), underlying generalized method of moments (GMM) estimators is a set of  $l$  moment conditions,  $E\{\mathbf{z}_i u_i(\boldsymbol{\beta})\} = \mathbf{0}$ . When  $l$  is greater than the number of parameters,  $k$ , any size- $k$  subset of the moment conditions would yield a consistent parameter estimate. We remarked that the parameter estimates we would obtain would in general depend on which  $k$  moment conditions we used. However, if all our moment conditions are indeed valid, then the parameter estimates should not differ too much regardless of which  $k$  moment conditions we used to estimate the parameters. The test of overidentifying restrictions is a model specification test based on this observation. The test of overidentifying restrictions requires that the number of moment conditions be greater than the number of parameters in the model.

Recall that the GMM criterion function is

$$Q = \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\boldsymbol{\beta}) \right\}' \mathbf{W} \left\{ \frac{1}{N} \sum_i \mathbf{z}_i u_i(\boldsymbol{\beta}) \right\}$$

The test of overidentifying restrictions is remarkably simple. If  $\mathbf{W}$  is an optimal weight matrix, under the null hypothesis  $H_0: E\{\mathbf{z}_i u_i(\boldsymbol{\beta})\} = \mathbf{0}$ , the test statistic  $J = N \times Q \sim \chi^2(l - k)$ . A large test statistic casts doubt on the null hypothesis.

For the test to be valid,  $\mathbf{W}$  must be optimal, meaning that  $\mathbf{W}$  must be the inverse of the covariance matrix of the moment conditions:

$$\mathbf{W}^{-1} = E\{\mathbf{z}_i u_i(\boldsymbol{\beta}) u_i'(\boldsymbol{\beta}) \mathbf{z}_i'\}$$

Therefore, `estat overid` works only after the two-step and iterated estimators, or if you supplied your own initial weight matrix by using the `winitial(matname)` option to `gmm` and used the one-step estimator.

Often the overidentifying restrictions test is interpreted as a test of the validity of the instruments  $\mathbf{z}$ . However, other forms of model misspecification can sometimes lead to a significant test statistic. See Hall (2005, sec. 5.1) for a discussion of the overidentifying restrictions test and its behavior in correctly and misspecified models.

### ▷ Example 1

In [example 6](#) of [\[R\] gmm](#), we fit an exponential regression model of the number of doctor visits based on the person's gender, income, possession of private health insurance, and presence of a chronic disease. We argued that the variable `income` may be endogenous; we used the person's age and race as additional instrumental variables. Here we refit the model and test the specification of the model. We type

```
. use https://www.stata-press.com/data/r19/docvisits
. gmm (docvis - exp({xb:private chronic female income} + {b0})),
> instruments(private chronic female age black hispanic)
(output omitted)
. estat overid
Test of overidentifying restriction:
Hansen's J chi2(2) = 9.52598 (p = 0.0085)
```

The  $J$  statistic is significant even at the 1% significance level, so we conclude that our model is misspecified. One possibility is that age and race directly affect the number of doctor visits, so we are not justified in excluding them from the model.

A simple technique to explore whether any of the instruments is invalid is to examine the statistics

$$r_j = \mathbf{W}_{jj}^{1/2} \left\{ \frac{1}{N} \sum_{i=1}^N z_{ij} u_i(\widehat{\boldsymbol{\beta}}) \right\}$$

for  $j = 1, \dots, k$ , where  $\mathbf{W}_{jj}$  denotes the  $j$ th diagonal element of  $\mathbf{W}$ ,  $u_i(\widehat{\boldsymbol{\beta}})$  denotes the sample residuals, and  $k$  is the number of instruments. If all the instruments are valid, then the scaled sample moments should at least be on the same order of magnitude. If one (or more) instrument's  $r_j$  is large in absolute value relative to the others, then that could be an indication that instrument is not valid.

In Stata, we type

```
. predict double r if e(sample), residuals // obtain residual from the model
. matrix W = e(W) // retrieve weight matrix
. local i 1
. // loop over each instrument and compute r_j
. foreach var of varlist private chronic female age black hispanic {
2. generate double r'var' = r*'var'*sqrt(W['i', 'i'])
3. local '++i'
4. }
. summarize r*
```

| Variable  | Obs   | Mean      | Std. dev. | Min       | Max      |
|-----------|-------|-----------|-----------|-----------|----------|
| r         | 4,412 | .0344373  | 8.26176   | -151.1847 | 113.059  |
| rprivate  | 4,412 | .007988   | 3.824118  | -72.66254 | 54.33852 |
| rchronic  | 4,412 | .0026947  | 2.0707    | -43.7311  | 32.703   |
| rfemale   | 4,412 | .0028168  | 1.566397  | -12.7388  | 24.43621 |
| rage      | 4,412 | .0360978  | 4.752986  | -89.74112 | 55.58143 |
| rblack    | 4,412 | -.0379317 | 1.062027  | -24.39747 | 27.34512 |
| rhispanic | 4,412 | -.017435  | 1.08567   | -5.509386 | 31.53512 |

We notice that the  $r_j$  statistics for age, black, and hispanic are larger than those for the other instruments in our model, supporting our suspicion that age and race may have a direct impact on the number of doctor visits.

## Stored results

estat overid stores the following in `r()`:

Scalars

|         |                                  |
|---------|----------------------------------|
| r(J)    | Hansen's $J$ statistic           |
| r(J_df) | $J$ statistic degrees of freedom |
| r(J_p)  | $J$ statistic $p$ -value         |

## Description

`grmeanby` graphs the (optionally weighted) means or medians of *varname* according to the values of the variables in *varlist*. The variables in *varlist* may be string or numeric and, if numeric, may be labeled.

## Quick start

Graph means of *v1* for each level of categorical variables *cvar1*, *cvar2*, and *cvar3*

```
grmeanby cvar1 cvar2 cvar3, sum(v1)
```

Same as above, but graph medians

```
grmeanby cvar1 cvar2 cvar3, sum(v1) median
```

Same as above, but use + as the marker

```
grmeanby cvar1 cvar2 cvar3, sum(v1) median msymbol(+)
```

## Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Graph means/medians by groups

## Syntax

```
grmeanby varlist [if] [in] [weight], summarize(varname) [options]
```

| <i>options</i>                          | Description                                                                        |

| Main                                    |                                                                                    |
| * <u>summarize</u> ( <i>varname</i> )   | graph mean (or median) of <i>varname</i>                                           |
| <u>median</u>                           | graph medians; default is to graph means                                           |
| Plot                                    |                                                                                    |
| <i>cline_options</i>                    | change look of the lines                                                           |
| <i>marker_options</i>                   | change look of markers (color, size, etc.)                                         |
| <i>marker_label_options</i>             | add marker labels; change look or position                                         |
| Y axis, X axis, Titles, Legend, Overall |                                                                                    |
| <i>twoway_options</i>                   | any options other than <code>by()</code> documented in [G-3] <i>twoway_options</i> |

\*`summarize`(*varname*) is required.

`aweights` and `fweights` are allowed; see [U] 11.1.6 **weight**.

## Options

### Main

`summarize`(*varname*) is required; it specifies the name of the variable whose mean or median is to be graphed.

`median` specifies that the graph is to be of medians, not means.

### Plot

*cline\_options* affect the rendition of the lines through the markers, including their color, pattern, and width; see [G-3] *cline\_options*.

*marker\_options* affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker\_options*.

*marker\_label\_options* specify if and how the markers are to be labeled; see [G-3] *marker\_label\_options*.

### Y axis, X axis, Titles, Legend, Overall

*twoway\_options* are any of the options documented in [G-3] *twoway\_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title\_options*) and for saving the graph to disk (see [G-3] *saving\_option*).

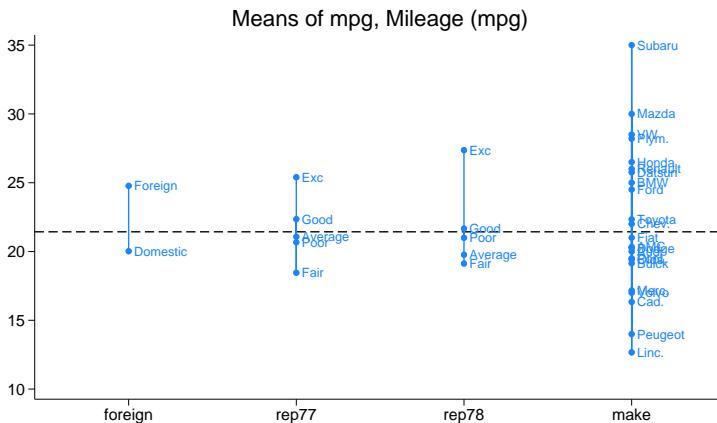

## Remarks and examples

The idea of graphing means of categorical variables was shown in [Chambers and Hastie \(1992, 3\)](#). Because this was shown in the context of an S function for making such graphs, it doubtless has roots going back further than that. `grmeanby` is, in any case, another implementation of what we will assume is their idea.

### ▶ Example 1

Using a variation of our auto dataset, we graph the mean of mpg by `foreign`, `rep77`, `rep78`, and `make`:

```
. use https://www.stata-press.com/data/r19/auto1
(Automobile models)
. grmeanby foreign rep77 rep78 make, sum(mpg)
```

If we had wanted a graph of medians rather than means, we could have typed

```
. grmeanby foreign rep77 rep78 make, sum(mpg) median
```

## Description

`hausman` performs Hausman's (1978) specification test.

## Quick start

Hausman test for stored models `consistent` and `efficient`

```
hausman consistent efficient
```

Same as above, but compare fixed-effects and random-effects linear regression models

```
hausman fixed random, sigmamore
```

Endogeneity test after `ivprobit` and `probit` with estimates stored in `iv` and `noiv`

```
hausman iv noiv, equations(1:1)
```

Test of independence of irrelevant alternatives for model with all alternatives `all` and model with omitted alternative `omitted`

```
hausman omitted all, alleqs constant
```

## Menu

Statistics > Postestimation

## Syntax

```
hausman name-consistent [name-efficient] [, options]
```

*name-consistent* and *name-efficient* are names under which estimation results were stored via `estimates store`; see [R] [estimates store](#). A period (.) may be used to refer to the last estimation results, even if these were not already stored. Not specifying *name-efficient* is equivalent to specifying the last estimation results as “.”.

| <i>options</i>                              | Description                                                                                   |

| <code>constant</code>                       | include estimated intercepts in comparison; default is to exclude                             |
| <code>alleqs</code>                         | use all equations to perform test; default is first equation only                             |
| <code>skipeqs</code> ( <i>eqlist</i> )      | skip specified equations when performing test                                                 |
| <code>equations</code> ( <i>matchlist</i> ) | associate/compare the specified (by number) pairs of equations                                |
| <code>force</code>                          | force performance of test, even though assumptions are not met                                |
| <code>df</code> (#)                         | use # degrees of freedom                                                                      |
| <code>sigmamore</code>                      | base both (co)variance matrices on disturbance variance<br>estimate from efficient estimator  |
| <code>sigmaless</code>                      | base both (co)variance matrices on disturbance variance<br>estimate from consistent estimator |
| Advanced                                    |                                                                                               |
| <code>tconsistent</code> ( <i>string</i> )  | consistent estimator column header                                                            |
| <code>tefficient</code> ( <i>string</i> )   | efficient estimator column header                                                             |

`collect` is allowed; see [U] [11.1.10 Prefix commands](#).

## Options

### Main

`constant` specifies that the estimated intercept(s) be included in the model comparison; by default, they are excluded. The default behavior is appropriate for models in which the constant does not have a common interpretation across the two models.

`alleqs` specifies that all the equations in the models be used to perform the Hausman test; by default, only the first equation is used.

`skipeqs` (*eqlist*) specifies in *eqlist* the names of equations to be excluded from the test. Equation numbers are not allowed in this context, because the equation names, along with the variable names, are used to identify common coefficients.

`equations(matchlist)` specifies, by number, the pairs of equations that are to be compared.

The *matchlist* in `equations()` should follow the syntax

$$\#_c : \#_e [ , \#_c : \#_e [ , \dots ] ]$$

where  $\#_c$  ( $\#_e$ ) is an equation number of the always-consistent (efficient under  $H_0$ ) estimator. For instance, `equations(1:1)`, `equations(1:1, 2:2)`, or `equations(1:2)`.

If `equations()` is not specified, then equations are matched on equation names.

`equations()` handles the situation in which one estimator uses equation names and the other does not. For instance, `equations(1:2)` means that equation 1 of the always-consistent estimator is to be tested against equation 2 of the efficient estimator. `equations(1:1, 2:2)` means that equation 1 is to be tested against equation 1 and that equation 2 is to be tested against equation 2. If `equations()` is specified, the `alleqs` and `skipeqs` options are ignored.

`force` specifies that the Hausman test be performed, even though the assumptions of the Hausman test seem not to be met, for example, because the estimators were `pweighted` or the data were clustered.

`df(#)` specifies the degrees of freedom for the Hausman test. The default is the matrix rank of the variance of the difference between the coefficients of the two estimators.

`sigmamore` and `sigmaless` specify that the two covariance matrices used in the test be based on a common estimate of disturbance variance ( $\sigma^2$ ).

`sigmamore` specifies that the covariance matrices be based on the estimated disturbance variance from the efficient estimator. This option provides a proper estimate of the contrast variance for so-called tests of exogeneity and overidentification in instrumental-variables regression.

`sigmaless` specifies that the covariance matrices be based on the estimated disturbance variance from the consistent estimator.

These options can be specified only when both estimators store `e(sigma)` or `e(rmse)`, or with the `xtreg` command. `e(sigma_e)` is stored after the `xtreg` command with the `fe` or `mle` option. `e(rmse)` is stored after the `xtreg` command with the `re` option.

`sigmamore` or `sigmaless` are recommended when comparing fixed-effects and random-effects linear regression because they are much less likely to produce a non-positive-definite-differenced covariance matrix (although the tests are asymptotically equivalent whether or not one of the options is specified).

---

Advanced

`tconsistent(string)` and `tefficient(string)` are formatting options. They allow you to specify the headers of the columns of coefficients that default to the names of the models. These options will be of interest primarily to programmers.

## Remarks and examples

`hausman` is a general implementation of Hausman's (1978) specification test, which compares an estimator  $\hat{\theta}_1$  that is known to be consistent with an estimator  $\hat{\theta}_2$  that is efficient under the assumption being tested. The null hypothesis is that the estimator  $\hat{\theta}_2$  is indeed an efficient (and consistent) estimator of the true parameters. If this is the case, there should be no systematic difference between the two estimators. If there exists a systematic difference in the estimates, you have reason to doubt the assumptions on which the efficient estimator is based.

The assumption of efficiency is violated if the estimator is `pweighted` or the data are clustered, so `hausman` cannot be used. The test can be forced by specifying the `force` option with `hausman`. For an alternative to using `hausman` in these cases, see [R] [suest](#).

To use `hausman`, you

```
. (compute the always-consistent estimator)
. estimates store name-consistent
. (compute the estimator that is efficient under H_0)
. hausman name-consistent .
```

Alternatively, you can turn this around:

```
. (compute the estimator that is efficient under H_0)
. estimates store name-efficient
. (fit the less-efficient model)
. (compute the always-consistent estimator)
. hausman . name-efficient
```

You can, of course, also compute and store both the always-consistent and efficient-under- $H_0$  estimators and perform the Hausman test with

```
. hausman name-consistent name-efficient
```

### ▷ Example 1

We are studying the factors that affect the wages of young women in the United States between 1968 and 1988, and we have a panel-data sample of individual women over that time span.

```
. use https://www.stata-press.com/data/r19/nlswork4
(National Longitudinal Survey of Young Women, 14-24 years old in 1968)
. describe

| sigma_e | .29751014                                   |           |       |       |                      |           |
| rho     | .61591044 (fraction of variance due to u_i) |           |       |       |                      |           |

F test that all u\_i=0: F(4709, 23781) = 7.76                      Prob > F = 0.0000

We assume that this model is consistent for the true parameters and store the results by using `estimates store` under a name, `fixed`:

```
. estimates store fixed
```

Now we fit a random-effects model as a fully efficient specification of the individual effects under the assumption that they are random and follow a normal distribution. We then compare these estimates with the previously stored results by using the `hausman` command.

```
. xtreg ln_wage age msp ttl_exp, re
Random-effects GLS regression Number of obs = 28,494

Prob > chi2 = 0.0000

Under the current specification, our initial hypothesis that the individual-level effects are adequately modeled by a random-effects model is resoundingly rejected. This result is based on the rest of our model specification, and random effects might be appropriate for some alternate model of wages.

◀

Jerry Allen Hausman (1946–) is an American economist and econometrician. He was born in West Virginia and went on to study economics at Brown and Oxford. He joined the MIT faculty in 1972 and continues to teach there. He currently researches new goods and their effects on consumer welfare and its measurement in the Consumer Price Index along with regulation and competition in the telecommunications industry.

Hausman is best known for his many contributions to econometrics. In 1978, he published his now famous paper giving the Hausman specification test. The work remains one of the most widely cited econometrics papers. He has also done extensive work in applied microeconomics pertaining to government's role in the economy, including antitrust regulation, public finance, and taxation.

In 1980, Hausman received the Frisch Medal, a biennial award from the Econometric Society recognizing exceptional applied work, for his paper with David Wise on attrition bias. In 1985, he won the John Bates Clark Award from the American Economics Association, which is given for outstanding contributions to economics by an economist under 40 years of age. In 2012, the *Advances in Econometrics* book series devoted an entire volume to Hausman and his contributions to econometrics.

## ▷ Example 2

A stringent assumption of multinomial and conditional logit models is that outcome categories for the model have the property of independence of irrelevant alternatives (IIA). Stated simply, this assumption requires that the inclusion or exclusion of categories does not affect the relative risks associated with the regressors in the remaining categories.

One classic example of a situation in which this assumption would be violated involves the choice of transportation mode; see [McFadden \(1974\)](#). For simplicity, postulate a transportation model with the four possible outcomes: rides a train to work, takes a bus to work, drives the Ford to work, and drives the Chevrolet to work. Clearly, “drives the Ford” is a closer substitute to “drives the Chevrolet” than it is to “rides a train” (at least for most people). This means that excluding “drives the Ford” from the model could be expected to affect the relative risks of the remaining options and that the model would not obey the IIA assumption.

Using the data presented in [\[R\] mlogit](#), we will use a simplified model to test for IIA. The choice of insurance type among indemnity, prepaid, and uninsured is modeled as a function of age and gender. The indemnity category is allowed to be the base category, and the model including all three outcomes is fit. The results are then stored under the name `allcats`.

```
. estimates store allcats
```

Under the IIA assumption, we would expect no systematic change in the coefficients if we excluded one of the outcomes from the model. (For an extensive discussion, see [Hausman and McFadden \[1984\]](#).) We reestimate the parameters, excluding the uninsured outcome, and perform a Hausman test against the fully efficient full model.

b = Consistent under H0 and Ha; obtained from **mlogit**.

B = Inconsistent under Ha, efficient under H0; obtained from **mlogit**.

Test of H0: Difference in coefficients not systematic

$$\begin{aligned} \text{chi2}(3) &= (b-B)' [(V_b-V_B)^{-1}] (b-B) \\ &= 0.08 \end{aligned}$$

Prob > chi2 = 0.9944

(V\_b-V\_B is not positive definite)

The syntax of the `if` condition on the `mlogit` command simply identified the "Uninsured" category with the `insure` value label; see [\[U\] 12.6.3 Value labels](#). On examining the output from `hausman`, we see that there is no evidence that the IIA assumption has been violated.

Because the Hausman test is a standardized comparison of model coefficients, using it with `mlogit` requires that the base outcome be the same in both competing models. In particular, if the most-frequent category (the default base outcome) is being removed to test for IIA, you must use the `baseoutcome()` option in `mlogit` to manually set the base outcome to something else. Or you can use the `equation()` option of the `hausman` command to align the equations of the two models.

Having the missing values for the square root of the diagonal of the covariance matrix of the differences is not comforting, but it is also not surprising. This covariance matrix is guaranteed to be positive definite only asymptotically (it is a consequence of the assumption that one of the estimators is efficient), and assurances are not made about the diagonal elements. Negative values along the diagonal are possible, and the fourth column of the table is provided mainly for descriptive use.

We can also perform the Hausman IIA test against the remaining alternative in the model:

```
. mlogit insure age male if insure != "Prepaid":insure

Test of H0: Difference in coefficients not systematic

```
chi2(3) = (b-B)' [(V_b-V_B)^(-1)](b-B)
 = -0.18
```

Warning: chi2 < 0 ==> model fitted on these data  
 fails to meet the asymptotic assumptions  
 of the Hausman test; see **suest** for a  
 generalized test.

Here the  $\chi^2$  statistic is actually negative. We might interpret this result as strong evidence that we cannot reject the null hypothesis. Such a result is not an unusual outcome for the Hausman test, particularly when the sample is relatively small—there are only 45 uninsured individuals in this dataset.

Are we surprised by the results of the Hausman test in this example? Not really. Judging from the  $z$  statistics on the original multinomial logit model, we were struggling to identify any structure in the data with the current specification. Even when we were willing to assume IIA and computed the efficient estimator under this assumption, few of the effects could be identified as statistically different from those on the base category. Trying to base a Hausman test on a contrast (difference) between two poor estimates is just asking too much of the existing data.

In [example 2](#), we encountered a case in which the Hausman was not well defined. Unfortunately, in our experience this happens fairly often. Stata provides an alternative to the Hausman test that overcomes this problem through an alternative estimator of the variance of the difference between the two estimators. This other estimator is guaranteed to be positive semidefinite. This alternative estimator also allows a widening of the scope of problems to which Hausman-type tests can be applied by relaxing the assumption that one of the estimators is efficient. For instance, you can perform Hausman-type tests to clustered observations and survey estimators. See [\[R\] suest](#) for details.

## Stored results

hausman stores the following in `r()`:

Scalars

|                      |                                      |
|----------------------|--------------------------------------|
| <code>r(chi2)</code> | $\chi^2$                             |
| <code>r(df)</code>   | degrees of freedom for the statistic |
| <code>r(p)</code>    | $p$ -value for the $\chi^2$          |
| <code>r(rank)</code> | rank of $(V_b - V_B)^{-1}$           |

## Methods and formulas

The Hausman statistic is distributed as  $\chi^2$  and is computed as

$$H = (\beta_c - \beta_e)'(V_c - V_e)^{-1}(\beta_c - \beta_e)$$

where

|           |                                                         |
|-----------|---------------------------------------------------------|
| $\beta_c$ | is the coefficient vector from the consistent estimator |
| $\beta_e$ | is the coefficient vector from the efficient estimator  |
| $V_c$     | is the covariance matrix of the consistent estimator    |
| $V_e$     | is the covariance matrix of the efficient estimator     |

When the difference in the variance matrices is not positive definite, a Moore–Penrose generalized inverse is used. As noted in [Gouriéroux and Monfort \(1995, 125–128\)](#), the choice of generalized inverse is not important asymptotically.

The number of degrees of freedom for the statistic is the rank of the difference in the variance matrices. When the difference is positive definite, this is the number of common coefficients in the models being compared.

## Acknowledgment

Portions of `hausman` are based on an early implementation by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

[Description](#)[Menu](#)[Options for Heckman selection model \(ML\)](#)[Remarks and examples](#)[Methods and formulas](#)[Also see](#)[Quick start](#)[Syntax](#)[Options for Heckman selection model \(two-step\)](#)[Stored results](#)[References](#)

## Description

`heckman` fits regression models with selection by using either Heckman's two-step consistent estimator or full maximum likelihood.

## Quick start

Heckman model of  $y$  on  $x_1$  with  $v_1$  predicting selection when binary variable `selected` indicates selection status

```
heckman y x1, select(selected = v1 x1)
```

Same as above, and generate  $v_2$  containing the inverse of Mills's ratio

```
heckman y x1, select(selected = v1 x1) mills(v2)
```

Same as above

```
heckman y x1, select(selected = v1 x1) nshazard(v2)
```

Fit a Heckman model using the two-step estimation method

```
heckman y x1, select(selected = v1 x1) twostep
```

Same as above, and display first-stage probit estimates

```
heckman y x1, select(selected = v1 x1) twostep first
```

## Menu

Statistics > Sample-selection models > Heckman selection model

## Syntax

### Basic syntax

```
heckman depvar [indepvars], select(varlists) [twostep]
```

or

```
heckman depvar [indepvars], select(depvars = varlists) [twostep]
```

### Full syntax for maximum likelihood estimates only

```
heckman depvar [indepvars] [if] [in] [weight],
select([depvars =] varlists [, noconstant offset(varnameo)]) [heckman_ml_options]
```

### Full syntax for Heckman's two-step consistent estimates only

```
heckman depvar [indepvars] [if] [in], twostep
select([depvars =] varlists [, noconstant]) [heckman_ts_options]
```

\*`twostep` and `select()` are required.

The full specification is `select([depvars =] varlists [, noconstant])`.

*indepvars* and *varlist<sub>s</sub>* may contain factor variables; see [U] 11.4.3 Factor variables.

*depvar*, *indepvars*, *varlist<sub>s</sub>*, and *depvar<sub>s</sub>* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: heckman.

Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.

`twostep`, `vce()`, `first`, `lrmmodel`, and `weights` are not allowed with the `svy` prefix; see [SVY] svy.

`pweights`, `fweights`, and `iweights` are allowed with maximum likelihood estimation; see [U] 11.1.6 weight. No weights are allowed if `twostep` is specified.

`collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options for Heckman selection model (ML)

### Model

`mle` requests that the maximum likelihood estimator be used. This is the default.

`select( [ depvars = ] varlists [ , noconstant offset(varnameo) ] )` specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If *depvar*<sub>s</sub> is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If *depvar*<sub>s</sub> is not specified, observations for which *depvar* is not missing are assumed selected, and those for which *depvar* is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`offset(varnameo)` specifies that selection offset *varname*<sub>o</sub> be included in the model with the coefficient constrained to be 1.

`noconstant`, `offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`first` specifies that the first-step probit estimates of the selection equation be displayed before estimation.

`lrmodel`; see [R] [Estimation options](#).

`nshazard(newvar)` and `mills(newvar)` are synonyms; either will create a new variable containing the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default *vcetype* to `vce(opg)`.

The following options are available with `heckman` but are not shown in the dialog box: `collinear`, `coeflegend`; see [R] [Estimation options](#).

## Options for Heckman selection model (two-step)

### Model

`twostep` specifies that Heckman's (1979) two-step efficient estimates of the parameters, standard errors, and covariance matrix be produced.

`select( [ depvars = ] varlists [ , noconstant ] )` specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If *depvar*<sub>s</sub> is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If *depvar*<sub>s</sub> is not specified, observations for which *depvar* is not missing are assumed selected, and those for which *depvar* is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`noconstant`; see [R] [Estimation options](#).

`rhosigma`, `rot trunc`, `rho limited`, and `rho force` are rarely used options to specify how the two-step estimator (option `twostep`) handles unusual cases in which the two-step estimate of  $\rho$  is outside the admissible range for a correlation,  $[-1, 1]$ . When  $\text{abs}(\rho) > 1$ , the two-step estimate of the coefficient variance–covariance matrix may not be positive definite and thus may be unusable for testing. The default is `rhosigma`.

`rhosigma` specifies that  $\rho$  be truncated, as with the `rot trunc` option, and that the estimate of  $\sigma$  be made consistent with  $\hat{\rho}$ , the truncated estimate of  $\rho$ . So,  $\hat{\sigma} = \beta_m \hat{\rho}$ ; see [Methods and formulas](#) for the definition of  $\beta_m$ . Both the truncated  $\rho$  and the new estimate of  $\hat{\sigma}$  are used in all computations to estimate the two-step covariance matrix.

`rot trunc` specifies that  $\rho$  be truncated to lie in the range  $[-1, 1]$ . If the two-step estimate is less than  $-1$ ,  $\rho$  is set to  $-1$ ; if the two-step estimate is greater than 1,  $\rho$  is set to 1. This truncated value of  $\rho$  is used in all computations to estimate the two-step covariance matrix.

`rho limited` specifies that  $\rho$  be truncated only in computing the diagonal matrix **D** as it enters  $\mathbf{V}_{\text{twostep}}$  and **Q**; see [Methods and formulas](#). In all other computations, the untruncated estimate of  $\rho$  is used.

`rho force` specifies that the two-step estimate of  $\rho$  be retained, even if it is outside the admissible range for a correlation. This option may, in rare cases, lead to a non–positive-definite covariance matrix.

These options have no effect when estimation is by maximum likelihood, the default. They also have no effect when the two-step estimate of  $\rho$  is in the range  $[-1, 1]$ .

### SE

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`conventional`) and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

`vce(conventional)`, the default, uses the two-step variance estimator derived by Heckman.

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` specifies that the first-step probit estimates of the selection equation be displayed before estimation.

`nshazard(newvar)` and `mills(newvar)` are synonyms; either will create a new variable containing the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no!stretch`; see [R] [Estimation options](#).

The following option is available with `heckman` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

The Heckman selection model (Gronau 1974; Lewis 1974; Heckman 1976) assumes that there exists an underlying regression relationship,

$$y_j = \mathbf{x}_j\boldsymbol{\beta} + u_{1j} \qquad \text{regression equation}$$

The dependent variable, however, is not always observed. Rather, the dependent variable for observation  $j$  is observed if

$$\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0 \qquad \text{selection equation}$$

where

$$u_1 \sim N(0, \sigma)$$

$$u_2 \sim N(0, 1)$$

$$\text{corr}(u_1, u_2) = \rho$$

When  $\rho \neq 0$ , standard regression techniques applied to the first equation yield biased results. `heckman` provides consistent, asymptotically efficient estimates for all the parameters in such models.

In one classic example, the first equation describes the wages of women. Women choose whether to work, and thus, from our point of view as researchers, whether we observe their wages in our data. If women made this decision randomly, we could ignore that not all wages are observed and use ordinary regression to fit a wage model. Such an assumption of random participation, however, is unlikely to be true; women who would have low wages may be unlikely to choose to work, and thus the sample of observed wages is biased upward. In the jargon of economics, women choose not to work when their personal reservation wage is greater than the wage offered by employers. Thus, women who choose not to work might have even higher offer wages than those who do work—they may have high offer wages, but they have even higher reservation wages. We could tell a story that competency is related to wages, but competency is rewarded more at home than in the labor force.

In any case, in this problem—which is the paradigm for most such problems—a solution can be found if there are some variables that strongly affect the chances for observation (the reservation wage) but not the outcome under study (the offer wage). Such a variable might be the number of children in the home. (Theoretically, we do not need such identifying variables, but without them, we depend on functional form to identify the model. It would be difficult for anyone to take such results seriously because the functional form assumptions have no firm basis in theory.)

### ▷ Example 1

In the syntax for `heckman`, `depvar` and `indepvars` are the dependent variable and regressors for the underlying regression model to be fit ( $y = \mathbf{X}\beta$ ), and `varlists` are the variables ( $\mathbf{Z}$ ) thought to determine whether `depvar` is observed or unobserved (selected or not selected). In our female wage example, the number of children at home would be included in the second list. By default, `heckman` assumes that missing values (see [U] 12.2.1 Missing values) of `depvar` imply that the dependent variable is unobserved (not selected). With some datasets, it is more convenient to specify a binary variable (`depvars`) that identifies the observations for which the dependent is observed/selected (`depvars ≠ 0`) or not observed (`depvars = 0`); `heckman` will accommodate either type of data. Here we have a (fictional) dataset on 2,000 women, 1,343 of whom work:

```
. use https://www.stata-press.com/data/r19/womenwk
. summarize age educ married children wage
```

| Variable  | Obs   | Mean     | Std. dev. | Min     | Max      |
|-----------|-------|----------|-----------|---------|----------|
| age       | 2,000 | 36.208   | 8.28656   | 20      | 59       |
| education | 2,000 | 13.084   | 3.045912  | 10      | 20       |
| married   | 2,000 | .6705    | .4701492  | 0       | 1        |
| children  | 2,000 | 1.6445   | 1.398963  | 0       | 5        |
| wage      | 1,343 | 23.69217 | 6.305374  | 5.88497 | 45.80979 |

We will assume that the hourly wage is a function of education and age, whereas the likelihood of working (the likelihood of the wage being observed) is a function of marital status, the number of children at home, and (implicitly) the wage (via the inclusion of age and education, which we think determine the wage):

```

. heckman wage educ age, select(married children educ age)
Iteration 0: Log likelihood = -5178.7009
Iteration 1: Log likelihood = -5178.3049
Iteration 2: Log likelihood = -5178.3045
Heckman selection model Number of obs = 2,000
(regression model with sample selection) Selected = 1,343
 Nonselected = 657
 Wald chi2(2) = 508.44
Log likelihood = -5178.304 Prob > chi2 = 0.0000

```

```

heckman assumes that wage is the dependent variable and that the first variable list (educ and age) are the determinants of wage. The variables specified in the select() option (married, children, educ, and age) are assumed to determine whether the dependent variable is observed (the selection equation). Thus, we fit the model

$$\text{wage} = \beta_0 + \beta_1 \text{educ} + \beta_2 \text{age} + u_1$$

and we assumed that wage is observed if

$$\gamma_0 + \gamma_1 \text{married} + \gamma_2 \text{children} + \gamma_3 \text{educ} + \gamma_4 \text{age} + u_2 > 0$$

where  $u_1$  and  $u_2$  have correlation  $\rho$ .

The reported results for the wage equation are interpreted exactly as though we observed wage data for all women in the sample; the coefficients on age and education level represent the estimated marginal effects of the regressors in the underlying regression equation. The results for the two ancillary parameters require some explanation. `heckman` does not directly estimate  $\rho$ ; to constrain  $\rho$  within its valid limits, and for numerical stability during optimization, it estimates the inverse hyperbolic tangent of  $\rho$ :

$$\operatorname{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

This estimate is reported as `/athrho`. In the bottom panel of the output, `heckman` undoes this transformation for you: the estimated value of  $\rho$  is 0.7035061. The standard error for  $\rho$  is computed using the delta method, and its confidence intervals are the transformed intervals of `/athrho`.

Similarly,  $\sigma$ , the standard error of the residual in the wage equation, is not directly estimated; for numerical stability, `heckman` instead estimates  $\ln \sigma$ . The untransformed `sigma` is reported at the end of the output: 6.004797.

Finally, some researchers—especially economists—are used to the selectivity effect summarized not by  $\rho$  but by  $\lambda = \rho\sigma$ . `heckman` reports this, too, along with an estimate of the standard error and confidence interval.

◀

## □ Technical note

If each of the equations in the model had contained many regressors, the `heckman` command could have become long. An alternate way of specifying our wage model would be to use Stata's global macros. The following lines are an equivalent way of specifying our model:

```
. global wageeq "wage educ age"
. global seleq "married children educ age"
. heckman $wageeq, select($seleq)
 (output omitted)
```

□

## □ Technical note

The reported model  $\chi^2$  test is a Wald test that all coefficients in the regression model (except the constant) are 0. `heckman` is an estimation command, so you can use `test`, `testnl`, or `lrtest` to perform tests against whatever nested alternate model you choose; see [\[R\] test](#), [\[R\] testnl](#), and [\[R\] lrtest](#).

The estimation of  $\rho$  and  $\sigma$  in the forms  $\operatorname{atanh} \rho$  and  $\ln \sigma$  extends the range of these parameters to infinity in both directions, thus avoiding boundary problems during the maximization. Tests of  $\rho$  must be made in the transformed units. However, because  $\operatorname{atanh}(0) = 0$ , the reported test for  $\operatorname{atanh} \rho = 0$  is equivalent to the test for  $\rho = 0$ .

The likelihood-ratio test reported at the bottom of the output is an equivalent test for  $\rho = 0$  and is computationally the comparison of the joint likelihood of an independent probit model for the selection equation and a regression model on the observed wage data against the Heckman model likelihood. Because  $\chi^2 = 61.20$ , this clearly justifies the Heckman selection equation with these data.

□

## ▶ Example 2

This command supports the Huber/White/sandwich estimator of variance under the `vce(robust)` and `vce(cluster clustvar)` options or when `pweights` are used for population-weighted data; see [U] 20.22 Obtaining robust variance estimates. We can obtain robust standard errors for our wage model by specifying clustering on county of residence (the `county` variable).

```
. heckman wage educ age, select(married children educ age) vce(cluster county)
Iteration 0: Log pseudolikelihood = -5178.7009
Iteration 1: Log pseudolikelihood = -5178.3049
Iteration 2: Log pseudolikelihood = -5178.3045
Heckman selection model Number of obs = 2,000
(regression model with sample selection) Selected = 1,343
 Nonselected = 657
 Wald chi2(1) = .
Log pseudolikelihood = -5178.304 Prob > chi2 = .
 (Std. err. adjusted for 10 clusters in county)
```

| sigma     | 6.004797    | .155199             |        |       | 5.708189             | 6.316818  |
| lambda    | 4.224412    | .5186709            |        |       | 3.207835             | 5.240988  |

```
Wald test of indep. eqns. (rho = 0): chi2(1) = 38.81 Prob > chi2 = 0.0000
```

The robust standard errors tend to be a bit larger, but we notice no systematic differences. This finding is not surprising because the data were not constructed to have any county-specific correlations or any other characteristics that would deviate from the assumptions of the Heckman model.

### ► Example 3

Stata also produces Heckman's (1979) two-step efficient estimator of the model with the `twostep` option. Maximum likelihood estimation of the parameters can be time consuming with large datasets, and the two-step estimates may provide a good alternative in such cases. Continuing with the women's wage model, we can obtain the two-step estimates with Heckman's consistent covariance estimates by typing

```
. heckman wage educ age, select(married children educ age) twostep
Heckman selection model -- two-step estimates Number of obs = 2,000
(regression model with sample selection) Selected = 1,343
 Nonselected = 657
 Wald chi2(2) = 442.54
 Prob > chi2 = 0.0000
```

### □ Technical note

The Heckman selection model depends strongly on the model being correct, much more so than ordinary regression. Running a separate probit or logit for sample inclusion followed by a regression, referred to in the literature as the two-part model (Manning, Duan, and Rogers 1987)—not to be confused with Heckman's two-step procedure—is an especially attractive alternative if the regression part of the model arose because of taking a logarithm of zero values. When the goal is to analyze an underlying regression model or to predict the value of the dependent variable that would be observed in the absence of selection, however, the Heckman model is more appropriate. When the goal is to predict an actual response, the two-part model is usually the better choice.

The Heckman selection model can be unstable when the model is not properly specified or if a specific dataset simply does not support the model's assumptions. For example, let's examine the solution to another simulated problem.

```

```

The model has converged to a value of  $\rho$  that is 1.0—within machine-rounding tolerances. Given the form of the likelihood for the Heckman selection model, this implies a division by zero, and it is surprising that the model solution turns out as well as it does. Reparameterizing  $\rho$  has allowed the estimation to converge, but we clearly have problems with the estimates. Moreover, if this had occurred in a large dataset, waiting for convergence might take considerable time.

This dataset was not intentionally developed to cause problems. It is actually generated by a “Heckman process” and when generated starting from different random values can be easily estimated. The luck of the draw here merely led to data that, despite the source, did not support the assumptions of the Heckman model.

The two-step model is generally more stable when the data are problematic. It even tolerates estimates of  $\rho$  less than  $-1$  and greater than  $1$ . For these reasons, the two-step model may be preferred when exploring a large dataset. Still, if the maximum likelihood estimates cannot converge, or converge to a value of  $\rho$  that is at the boundary of acceptable values, there is scant support for fitting a Heckman selection model on the data. Heckman (1979) discusses the implications of  $\rho$  being exactly 1 or 0, together with the implications of other possible covariance relationships among the model’s determinants.

□

## Stored results

heckman (maximum likelihood) stores the following in `e()`:

In addition to the above, the following is stored in `r()`:

Matrices

`r(table)`

matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

James Joseph Heckman (1944–) was born in Chicago in 1944 and studied mathematics at Colorado College and economics at Princeton. He has taught economics at Columbia and (since 1973) at the University of Chicago. He has worked on developing a scientific basis for economic policy evaluation, with emphasis on models of individuals or disaggregated groups and the problems and possibilities created by heterogeneity, diversity, and unobserved counterfactual states. In 2000, he shared the Nobel Prize in Economics with Daniel L. McFadden.

## Methods and formulas

Cameron and Trivedi (2022, 974–981) and Greene (2018, 950–957) provide good introductions to the Heckman selection model. Adkins and Hill (2011, sec. 16.8) describe the two-step estimator with an application using Stata. Jones (2007, 35–40) illustrates Heckman estimation with an application to health economics.

Regression estimates using the nonselection hazard (Heckman 1979) provide starting values for maximum likelihood estimation.

The regression equation is

$$y_j = \mathbf{x}_j\boldsymbol{\beta} + u_{1j}$$

The selection equation is

$$\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0$$

where

$$u_1 \sim N(0, \sigma)$$

$$u_2 \sim N(0, 1)$$

$$\text{corr}(u_1, u_2) = \rho$$

The log likelihood for observation  $j$ ,  $\ln L_j = l_j$ , is

$$l_j = \begin{cases} w_j \ln \Phi \left\{ \frac{\mathbf{z}_j\boldsymbol{\gamma} + (y_j - \mathbf{x}_j\boldsymbol{\beta})\rho/\sigma}{\sqrt{1 - \rho^2}} \right\} - \frac{w_j}{2} \left( \frac{y_j - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right)^2 - w_j \ln(\sqrt{2\pi}\sigma) & y_j \text{ observed} \\ w_j \ln \Phi(-\mathbf{z}_j\boldsymbol{\gamma}) & y_j \text{ not observed} \end{cases}$$

where  $\Phi(\cdot)$  is the standard cumulative normal and  $w_j$  is an optional weight for observation  $j$ .

In the maximum likelihood estimation,  $\sigma$  and  $\rho$  are not directly estimated. Directly estimated are  $\ln \sigma$  and  $\text{atanh } \rho$ :

$$\text{atanh } \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

The standard error of  $\lambda = \rho\sigma$  is approximated through the propagation of error (delta) method; that is,

$$\text{Var}(\lambda) \approx \mathbf{D} \text{Var}\{\text{atanh } \rho \text{ ln } \sigma\} \mathbf{D}'$$

where  $\mathbf{D}$  is the Jacobian of  $\lambda$  with respect to  $\text{atanh } \rho$  and  $\ln \sigma$ .

With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] [\\_robust](#), particularly [Maximum likelihood estimators](#) and [Methods and formulas](#).

The maximum likelihood version of `heckman` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

The two-step estimates are computed using Heckman's (1979) procedure.

Probit estimates of the selection equation

$$\Pr(y_j \text{ observed} \mid \mathbf{z}_j) = \Phi(\mathbf{z}_j \boldsymbol{\gamma})$$

are obtained. From these estimates, the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio,  $m_j$ —for each observation  $j$  is computed as

$$m_j = \frac{\phi(\mathbf{z}_j \hat{\boldsymbol{\gamma}})}{\Phi(\mathbf{z}_j \hat{\boldsymbol{\gamma}})}$$

where  $\phi$  is the normal density. We also define

$$\delta_j = m_j(m_j + \hat{\boldsymbol{\gamma}} \mathbf{z}_j)$$

Following Heckman, the two-step parameter estimates of  $\boldsymbol{\beta}$  are obtained by augmenting the regression equation with the nonselection hazard  $\mathbf{m}$ . Thus, the regressors become  $[\mathbf{X} \ \mathbf{m}]$ , and we obtain the additional parameter estimate  $\boldsymbol{\beta}_m$  on the variable containing the nonselection hazard.

A consistent estimate of the regression disturbance variance is obtained using the residuals from the augmented regression and the parameter estimate on the nonselection hazard,

$$\hat{\sigma}^2 = \frac{\mathbf{e}'\mathbf{e} + \boldsymbol{\beta}_m^2 \sum_{j=1}^N \delta_j}{N}$$

The two-step estimate of  $\rho$  is then

$$\hat{\rho} = \frac{\boldsymbol{\beta}_m}{\hat{\sigma}}$$

Heckman derived consistent estimates of the coefficient covariance matrix on the basis of the augmented regression.

Let  $\mathbf{W} = [\mathbf{X} \mathbf{m}]$  and  $\mathbf{R}$  be a square, diagonal matrix of dimension  $N$ , with  $(1 - \hat{\rho}^2 \delta_j)$  as the diagonal elements. The conventional VCE is

$$\mathbf{V}_{\text{twostep}} = \hat{\sigma}^2 (\mathbf{W}'\mathbf{W})^{-1} (\mathbf{W}'\mathbf{R}\mathbf{W} + \mathbf{Q}) (\mathbf{W}'\mathbf{W})^{-1}$$

where

$$\mathbf{Q} = \hat{\rho}^2 (\mathbf{W}'\mathbf{D}\mathbf{Z}) \mathbf{V}_p (\mathbf{Z}'\mathbf{D}\mathbf{W})$$

where  $\mathbf{D}$  is the square, diagonal matrix of dimension  $N$  with  $\delta_j$  as the diagonal elements;  $\mathbf{Z}$  is the data matrix of selection equation covariates; and  $\mathbf{V}_p$  is the variance–covariance estimate from the probit estimation of the selection equation.

## Postestimation commands

The following postestimation commands are available after `heckman`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| * <code>estat ic</code>      | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| † <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * † <code>lrtest</code>      | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from <code>margins</code> (profile plots, interaction plots, etc.)                                                    |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | linear predictions and their SEs, probabilities, etc.                                                                                   |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| * <code>suest</code>         | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\* `estat ic`, `lrtest`, and `suest` are not appropriate after `heckman`, `twostep`.

† `hausman` and `lrtest` are not appropriate with `svy` estimation results.

## predict

### Description for predict

`predict` creates a new variable containing predictions such as linear predictions, standard errors, probabilities, expected values, and nonselection hazards.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

After ML or twostep

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

After ML

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i>                            | Description                                                    |
|---------------------------------------------|----------------------------------------------------------------|
| Main                                        |                                                                |
| <code>xb</code>                             | linear prediction; the default                                 |
| <code>stdp</code>                           | standard error of the prediction                               |
| <code>stdf</code>                           | standard error of the forecast                                 |
| <code>xbse1</code>                          | linear prediction for selection equation                       |
| <code>stdpse1</code>                        | standard error of the linear prediction for selection equation |
| <code>pr(a,b)</code>                        | $\Pr(y_j   a < y_j < b)$                                       |
| <code>e(a,b)</code>                         | $E(y_j   a < y_j < b)$                                         |
| <code>ystar(a,b)</code>                     | $E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\}$                    |
| <code>ycond</code>                          | $E(y_j   y_j \text{ observed})$                                |
| <code>yexpected</code>                      | $E(y_j^*), y_j$ taken to be 0 where unobserved                 |
| <code>nshazard</code> or <code>mills</code> | nonselection hazard (also called the inverse of Mills's ratio) |
| <code>pse1</code>                           | $\Pr(y_j \text{ observed})$                                    |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where  $a$  and  $b$  may be numbers or variables;  $a$  missing ( $a \geq .$ ) means  $-\infty$ , and  $b$  missing ( $b \geq .$ ) means  $+\infty$ ; see [U] 12.2.1 Missing values.

## Options for predict

Main

`xb`, the default, calculates the linear prediction  $\mathbf{x}_j\mathbf{b}$ .

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see [Methods and formulas](#) in [R] [regress postestimation](#).

`xbse1` calculates the linear prediction for the selection equation.

`stdpse1` calculates the standard error of the linear prediction for the selection equation.

`pr(a,b)` calculates  $\Pr(a < \mathbf{x}_j\mathbf{b} + u_1 < b)$ , the probability that  $y_j|\mathbf{x}_j$  would be observed in the interval  $(a,b)$ .

$a$  and  $b$  may be specified as numbers or variable names;  $lb$  and  $ub$  are variable names;

`pr(20,30)` calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_1 < 30)$ ; `pr(lb,ub)` calculates  $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_1 < ub)$ ; and `pr(20,ub)` calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_1 < ub)$ .

$a$  missing ( $a \geq .$ ) means  $-\infty$ ; `pr(.,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_1 < 30)$ ;

`pr(lb,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$  in observations for which  $lb \geq .$  and calculates  $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < 30)$  elsewhere.

$b$  missing ( $b \geq .$ ) means  $+\infty$ ; `pr(20,.)` calculates  $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$ ;

`pr(20,ub)` calculates  $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$  in observations for which  $ub \geq .$  and calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$  elsewhere.

`e(a,b)` calculates  $E(\mathbf{x}_j\mathbf{b} + u_1 | a < \mathbf{x}_j\mathbf{b} + u_1 < b)$ , the expected value of  $y_j|\mathbf{x}_j$  conditional on  $y_j|\mathbf{x}_j$  being in the interval  $(a,b)$ , meaning that  $y_j|\mathbf{x}_j$  is truncated.

$a$  and  $b$  are specified as they are for `pr()`.

`ystar(a,b)` calculates  $E(y_j^*)$ , where  $y_j^* = a$  if  $\mathbf{x}_j\mathbf{b} + u_j \leq a$ ,  $y_j^* = b$  if  $\mathbf{x}_j\mathbf{b} + u_j \geq b$ , and  $y_j^* = \mathbf{x}_j\mathbf{b} + u_j$  otherwise, meaning that  $y_j^*$  is censored.  $a$  and  $b$  are specified as they are for `pr()`.

`ycond` calculates the expected value of the dependent variable conditional on the dependent variable being observed, that is, selected;  $E(y_j | y_j \text{ observed})$ .

`yexpected` calculates the expected value of the dependent variable ( $y_j^*$ ), where that value is taken to be 0 when it is expected to be unobserved;  $y_j^* = \Pr(y_j \text{ observed})E(y_j | y_j \text{ observed})$ .

The assumption of 0 is valid for many cases where nonselection implies nonparticipation (for example, unobserved wage levels, insurance claims from those who are uninsured) but may be inappropriate for some problems (for example, unobserved disease incidence).

`nshazard` and `mills` are synonyms; both calculate the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio—from the selection equation.

`pse1` calculates the probability of selection (or being observed):

$$\Pr(y_j \text{ observed}) = \Pr(\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0).$$

scores, not available with `twostep`, calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j \boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j \boldsymbol{\gamma})$ .

The third new variable will contain  $\partial \ln L / \partial (\text{atanh } \rho)$ .

The fourth new variable will contain  $\partial \ln L / \partial (\ln \sigma)$ .

`nooffset` is relevant when you specify `offset(varname)` for `heckman`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j \mathbf{b}$  rather than as  $\mathbf{x}_j \mathbf{b} + \text{offset}_j$ .

## margins

### Description for margins

`margins` estimates margins of response for linear predictions, probabilities, expected values, and nonselection hazards.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>                                 | Description                                                    |
|--------------------------------------------------|----------------------------------------------------------------|
| <code>xb</code>                                  | linear prediction; the default                                 |
| <code>xbtsel</code>                              | linear prediction for selection equation                       |
| <code>pr(<i>a</i>,<i>b</i>)</code>               | $\Pr(y_j \mid a < y_j < b)$                                    |
| <code>e(<i>a</i>,<i>b</i>)</code>                | $E(y_j \mid a < y_j < b)$                                      |
| <code>y<sup>star</sup>(<i>a</i>,<i>b</i>)</code> | $E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\}$                    |
| * <code>ycond</code>                             | $E(y_j \mid y_j \text{ observed})$                             |
| * <code>yexpected</code>                         | $E(y_j^*), y_j$ taken to be 0 where unobserved                 |
| <code>nshazard</code> or <code>mills</code>      | nonselection hazard (also called the inverse of Mills's ratio) |
| <code>p<sup>sel</sup></code>                     | $\Pr(y_j \text{ observed})$                                    |
| <code>stdp</code>                                | not allowed with margins                                       |
| <code>stdf</code>                                | not allowed with margins                                       |
| <code>stdp<sup>sel</sup></code>                  | not allowed with margins                                       |

\*`ycond` and `yexpected` are not allowed with margins after `heckman`, `twostep`.

Statistics not allowed with margins are functions of stochastic quantities other than `e(b)`.

For the full syntax, see [R] [margins](#).

## Remarks and examples

### ▷ Example 1

The default statistic produced by `predict` after `heckman` is the expected value of the dependent variable from the underlying distribution of the regression model. In the `wage model` of [R] `heckman`, this is the expected wage rate among all women, regardless of whether they were observed to participate in the labor force:

```
. use https://www.stata-press.com/data/r19/womenwk
. heckman wage educ age, select(married children educ age) vce(cluster county)
 (output omitted)
. predict heckwage
 (option xb assumed; fitted values)
```

It is instructive to compare these predicted wage values from the Heckman model with an ordinary regression model—a model without the selection adjustment:

```
. regress wage educ age
```

| Source   | SS         | df    | MS         | Number of obs | = | 1,343  |

| wage      | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|-----------|-------------|-----------|-------|-------|----------------------|----------|
| education | .8965829    | .0498061  | 18.00 | 0.000 | .7988765             | .9942893 |
| age       | .1465739    | .0187135  | 7.83  | 0.000 | .109863              | .1832848 |
| _cons     | 6.084875    | .8896182  | 6.84  | 0.000 | 4.339679             | 7.830071 |

```
. predict regwage
 (option xb assumed; fitted values)
. summarize heckwage regwage
```

| Variable | Obs   | Mean     | Std. dev. | Min      | Max      |
|----------|-------|----------|-----------|----------|----------|
| heckwage | 2,000 | 21.15532 | 3.83965   | 14.6479  | 32.85949 |
| regwage  | 2,000 | 23.12291 | 3.241911  | 17.98218 | 32.66439 |

Because this dataset was concocted, we know the true coefficients of the wage regression equation to be 1, 0.2, and 1, respectively. We can compute the true mean wage for our sample.

```
. generate truewage = 1 + .2*age + 1*educ
. summarize truewage
```

| Variable | Obs   | Mean    | Std. dev. | Min | Max  |
|----------|-------|---------|-----------|-----|------|
| truewage | 2,000 | 21.3256 | 3.797904  | 15  | 32.8 |

Whereas the mean of the predictions from `heckman` is within 18 cents of the true mean wage, ordinary regression yields predictions that are on average about \$1.80 per hour too high because of the selection effect. The regression predictions also show somewhat less variation than the true wages.

The coefficients from heckman are so close to the true values that they are not worth testing. Conversely, the regression equation is significantly off but seems to give the right sense. Would we be led far astray if we relied on the OLS coefficients? The effect of age is off by more than 5 cents per year of age, and the coefficient on education level is off by about 10%. We can test the OLS coefficient on education level against the true value by using `test`.

```
. test educ = 1
(1) education = 1
 F(1, 1340) = 4.31
 Prob > F = 0.0380
```

The OLS coefficient on education is substantially lower than the true parameter; moreover, the difference from the true parameter is also statistically significant beyond the 5% level. We can perform a similar test for the OLS age coefficient:

```
. test age = .2
(1) age = .2
 F(1, 1340) = 8.15
 Prob > F = 0.0044
```

We find even stronger evidence that the OLS regression results are biased away from the true parameters.

## ▷ Example 2

Several other interesting aspects of the Heckman model can be explored with `predict`. Continuing with our wage model, we can obtain the expected wages for women conditional on participating in the labor force with the `ycond` option. Let's get these predictions and compare them with actual wages for women participating in the labor force.

```
. use https://www.stata-press.com/data/r19/womenwk, clear
. heckman wage educ age, select(married children educ age)
 (output omitted)
. predict hcndwage, ycond
. summarize wage hcndwage if wage != .
```

| Variable | Obs   | Mean     | Std. dev. | Min      | Max      |
|----------|-------|----------|-----------|----------|----------|
| wage     | 1,343 | 23.69217 | 6.305374  | 5.88497  | 45.80979 |
| hcndwage | 1,343 | 23.68239 | 3.335087  | 16.18337 | 33.7567  |

We see that the average predictions from heckman are close to the observed levels but do not have the same mean. These conditional wage predictions are available for all observations in the dataset but can be directly compared only with observed wages, where individuals are participating in the labor force.

What if we were interested in making predictions about mean wages for all women? Here the expected wage is 0 for those who are not expected to participate in the labor force, with expected participation determined by the selection equation. These values can be obtained with the `yexpected` option of `predict`. For comparison, a variable can be generated where the wage is set to 0 for nonparticipants.

```
. predict hexpwage, yexpected
. generate wage0 = wage
(657 missing values generated)
. replace wage0 = 0 if wage == .
(657 real changes made)
. summarize hexpwage wage0
```

| Variable | Obs   | Mean     | Std. dev. | Min      | Max      |
|----------|-------|----------|-----------|----------|----------|
| hexpwage | 2,000 | 15.92511 | 5.979336  | 2.492469 | 32.45858 |
| wage0    | 2,000 | 15.90929 | 12.27081  | 0        | 45.80979 |

Again we note that the predictions from heckman are close to the observed mean hourly wage rate for all women. Why aren't the predictions using `ycond` and `yexpected` equal to their observed sample equivalents? For the Heckman model, unlike linear regression, the sample moments implied by the optimal solution to the model likelihood do not require that these predictions match observed data. Properly accounting for the additional variation from the selection equation requires that the model use more information than just the sample moments of the observed wages.

## Description

`heckoprobit` fits maximum-likelihood ordered probit models with sample selection.

## Quick start

Ordered probit model of  $y$  on  $x$  with selection indicated by binary variable `selected` and predicted by  $v$

```
heckoprobit y x, select(selected = v x)
```

Add [indicator variables](#) for each level of categorical variable  $a$

```
heckoprobit y x i.a, select(selected = v x i.a)
```

Account for complex sampling design using [svyset](#) data

```
svy: heckoprobit y x, select(selected = v x)
```

## Menu

Statistics > Sample-selection models > Ordered probit model with selection

## Syntax

```
heckoprobit deprvar indepvars [if] [in] [weight] ,
 select([deprvars =] varlists [, noconstant offset(varnameo)]) [options]
```

| <u>collinear</u>                          | keep collinear variables                                                                                                                         |
| <u>coeflegend</u>                         | display legend instead of statistics                                                                                                             |

\*select( ) is required.

The full specification is select( [*deprvar*<sub>s</sub> = ] *varlist*<sub>s</sub> [ , noconstant offset(*varname*<sub>o</sub>) ] ).

*indepvars* and *varlist*<sub>s</sub> may contain factor variables; see [U] 11.4.3 **Factor variables**.

*deprvar*, *indepvars*, *deprvar*<sub>s</sub>, and *varlist*<sub>s</sub> may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

bayes, bayesboot, bootstrap, by, collect, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: heckoprobit**.

Weights are not allowed with the bootstrap prefix; see [R] **bootstrap**.

vce( ), first, and weights are not allowed with the svy prefix; see [SVY] **svy**.

pweights, fweights, and iweights are allowed; see [U] 11.1.6 **weight**.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options

### Model

`select( [ depvars = ] varlists [ , noconstant offset(varnameo) ] )` specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If *depvar*<sub>s</sub> is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If *depvar*<sub>s</sub> is not specified, observations for which *depvar* is not missing are assumed selected, and those for which *depvar* is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`offset(varnameo)` specifies that selection offset *varname*<sub>o</sub> be included in the model with the coefficient constrained to be 1.

`offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`first` specifies that the first-step probit estimates of the selection equation be displayed before estimation.

`noheader` suppresses the header above the parameter table.

`nofootnote` suppresses the footnotes displayed below the parameter table.

`nocnsreport`; see [R] [Estimation options](#).

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no!stretch`; see [R] [Estimation options](#).

### Maximization

*maximize\_options*: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrntolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default *vcetype* to `vce(opg)`.

The following options are available with `heckoprobit` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

`heckoprobit` estimates the parameters of a regression model for an ordered categorical outcome from a nonrandom sample known as a selected sample. Selected samples suffer from “selection on unobservables” because the errors that determine whether a case is missing are correlated with the errors that determine the outcome.

For ordered categorical regression from samples that do not suffer from selection on unobservables, see [R] [oprobit](#) or [R] [ologit](#). For regression of a continuous outcome variable from a selected sample, see [R] [heckman](#).

Even though we are interested in modeling a single ordinal outcome, there are two dependent variables in the ordered probit sample-selection model because we must also model the sample-selection process. First, there is the ordinal outcome  $y_j$ . Second, there is a binary variable that indicates whether each case in the sample is observed or unobserved. To handle the sample-selection problem, we model both dependent variables jointly. Both variables are categorical. Their categorical values are determined by the values of linear combinations of covariates and normally distributed error terms relative to certain cutpoints that partition the real line. The error terms used in the determination of selection and the ordinal outcome value may be correlated.

The probability that the ordinal outcome  $y_j$  is equal to the value  $v_h$  is given by the probability that  $\mathbf{x}_j\boldsymbol{\beta} + u_{1j}$  falls within the cutpoints  $\kappa_{h-1}$  and  $\kappa_h$ ,

$$\Pr(y_j = v_h) = \Pr(\kappa_{h-1} < \mathbf{x}_j\boldsymbol{\beta} + u_{1j} \leq \kappa_h)$$

where  $\mathbf{x}_j$  is the outcome covariates,  $\boldsymbol{\beta}$  is the coefficients, and  $u_{1j}$  is a random-error term. The observed outcome values  $v_1, \dots, v_H$  are integers such that  $v_i < v_m$  for  $i < m$ .  $\kappa_0$  is taken as  $-\infty$  and  $\kappa_H$  is taken as  $+\infty$ .

We model the selection process for the outcome by

$$s_j = \mathbf{1}(\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0)$$

where  $s_j = 1$  if we observed  $y_j$  and 0 otherwise,  $\mathbf{z}_j$  is the covariates used to model the selection process,  $\boldsymbol{\gamma}$  is the coefficients for the selection process,  $\mathbf{1}(\cdot)$  denotes the indicator function, and  $u_{2j}$  is a random-error term.

$(u_{1j}, u_{2j})$  have bivariate normal distribution with mean zero and variance matrix

$$\begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$$

When  $\rho \neq 0$ , standard ordered probit techniques applied to the outcome equation yield inconsistent results. `heckoprobit` provides consistent, asymptotically efficient estimates for all the parameters in such models.

[De Luca and Perotti \(2011\)](#) describe the maximum likelihood estimator used in `heckoprobit`.

## ▷ Example 1

We have a simulated dataset containing a sample of 5,000 women, 3,480 of whom work. The outcome of interest is a woman's job satisfaction, and we suspect that unobservables that determine job satisfaction and the unobservables that increase the likelihood of employment are correlated. Women may make a decision to work based on how satisfying their job would be. We estimate the parameters of an ordered probit sample-selection model for the outcome of job satisfaction (`satisfaction`) with selection on employment (`work`). Age (`age`) and years of education (`education`) are used as outcome covariates, and we also expect that they affect selection. Additional covariates for selection are marital status (`married`) and the number of children at home (`children`).

Here we estimate the parameters of the model with `heckoprobit`. We use the factorial interaction of `married` and `children` in `select()`. This specifies that the number of children and marital status affect selection, and it allows the effect of the number of children to differ among married and nonmarried women. The factorial interaction is specified using factor-variable notation, which is described in [U] 11.4.3 **Factor variables**.

```

```

LR test of indep. eqns. (rho = 0): chi2(1) = 88.10 Prob > chi2 = 0.0000

```

The output shows several iteration logs. The first iteration log corresponds to running the ordered probit model for those observations in the sample where we have observed the outcome. The second iteration log corresponds to running the selection probit model, which models whether we observe our outcome of interest. If  $\rho = 0$ , the sum of the log likelihoods from these two models will equal the log likelihood of the ordered probit sample-selection model; this sum is printed in the iteration log as the comparison log likelihood. The final iteration log is for fitting the full ordered probit sample-selection model.

The Wald test in the header is highly significant, indicating a good model fit. All the covariates are statistically significant. The likelihood-ratio test in the footer indicates that we can reject the null hypothesis that the errors for outcome and selection are uncorrelated. This means that we should use the ordered probit sample-selection model instead of the simple ordered probit model.

The positive estimate of 0.63 for  $\rho$  indicates that unobservables that increase job satisfaction tend to occur with unobservables that increase the chance of having a job.

## Stored results

heckoprobit stores the following in `e()`:

### Matrices

|                          |                                     |
|--------------------------|-------------------------------------|
| <code>e(b)</code>        | coefficient vector                  |
| <code>e(Cns)</code>      | constraints matrix                  |
| <code>e(ilog)</code>     | iteration log (up to 20 iterations) |
| <code>e(gradient)</code> | gradient vector                     |

|                 |                                              |
|-----------------|----------------------------------------------|
| e(cat)          | category values                              |
| e(V)            | variance–covariance matrix of the estimators |
| e(V_modelbased) | model-based variance                         |
| Functions       |                                              |
| e(sample)       | marks estimation sample                      |

In addition to the above, the following is stored in `r()`:

|          |                                                                                                                       |
|----------|-----------------------------------------------------------------------------------------------------------------------|
| Matrices |                                                                                                                       |
| r(table) | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any  $r$ -class command is run after the estimation command.

## Methods and formulas

De Luca and Perotti (2011) provide an introduction to this model.

The ordinal outcome equation is

$$y_j = \sum_{h=1}^H v_h 1(\kappa_{h-1} < \mathbf{x}_j \boldsymbol{\beta} + u_{1j} \leq \kappa_h)$$

where  $\mathbf{x}_j$  is the outcome covariates,  $\boldsymbol{\beta}$  is the coefficients, and  $u_{1j}$  is a random-error term. The observed outcome values  $v_1, \dots, v_H$  are integers such that  $v_i < v_m$  for  $i < m$ .  $\kappa_1, \dots, \kappa_{H-1}$  are real numbers such that  $\kappa_i < \kappa_m$  for  $i < m$ .  $\kappa_0$  is taken as  $-\infty$  and  $\kappa_H$  is taken as  $+\infty$ .

The selection equation is

$$s_j = \mathbf{1}(z_j \boldsymbol{\gamma} + u_{2j} > 0)$$

where  $s_j = 1$  if we observed  $y_j$  and 0 otherwise,  $z_j$  is the covariates used to model the selection process,  $\boldsymbol{\gamma}$  is the coefficients for the selection process, and  $u_{2j}$  is a random-error term.

$(u_{1j}, u_{2j})$  have bivariate normal distribution with mean zero and variance matrix

$$\begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$$

Let  $a_j = z_j \boldsymbol{\gamma} + \text{offset}_j^\gamma$  and  $b_j = x_j \boldsymbol{\beta} + \text{offset}_j^\beta$ . This yields the log likelihood

$$\ln L = \sum_{j \notin S} w_j \ln \{ \Phi(-a_j) \} + \sum_{h=1}^H \sum_{\substack{j \in S \\ y_j = v_h}} w_j \ln \{ \Phi_2(a_j, \kappa_h - b_j, -\rho) - \Phi_2(a_j, \kappa_{h-1} - b_j, -\rho) \}$$

where  $S$  is the set of observations for which  $y_j$  is observed,  $\Phi_2(\cdot)$  is the cumulative bivariate normal distribution function (with mean  $[0 \ 0]'$ ),  $\Phi(\cdot)$  is the standard cumulative normal, and  $w_j$  is an optional weight for observation  $j$ .

In the maximum likelihood estimation,  $\rho$  is not directly estimated. Directly estimated is  $\text{atanh } \rho$ :

$$\text{atanh } \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

From the form of the likelihood, it is clear that if  $\rho = 0$ , the log likelihood for the ordered probit sample-selection model is equal to the sum of the ordered probit model for the outcome  $y$  and the selection model. We can perform a likelihood-ratio test by comparing the log likelihood of the full model with the sum of the log likelihoods for the ordered probit and selection models.

## Postestimation commands

The following postestimation commands are available after `heckoprobit`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | probabilities, linear predictions and their SEs, etc.                                                                                   |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |

| <code>stdp</code>       | standard error of the linear prediction                        |
| <code>xbselect</code>   | linear prediction for selection equation                       |
| <code>stdpselect</code> | standard error of the linear prediction for selection equation |

---

If you do not specify `outcome()`, `pmargin` (with one new variable specified) assumes `outcome(#1)`.

You specify one or  $k$  new variables with `pmargin`, where  $k$  is the number of outcomes.

You specify one new variable with `pselect`, `xb`, `stdp`, `xbselect`, and `stdpselect`.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`pmargin`, the default, calculates the predicted marginal probabilities.

You specify one or  $k$  new variables, where  $k$  is the number of categories of the outcome variable  $y_j$ . If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the marginal probability that  $y_j$  is equal to the level `outcome()` is calculated. When `outcome()` is not specified, the marginal probabilities for each outcome level are calculated.

`p1` calculates the predicted bivariate probabilities of outcome levels with selection.

You specify one or  $k$  new variables, where  $k$  is the number of categories of the outcome variable  $y_j$ . If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the bivariate probability that  $y_j$  is equal to the level `outcome()` and that  $y_j$  is observed is calculated. When `outcome()` is not specified, the bivariate probabilities for each outcome level and selection are calculated.

`p0` calculates the predicted bivariate probabilities of outcome levels with no selection.

You specify one or  $k$  new variables, where  $k$  is the number of categories of the outcome variable  $y_j$ . If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the bivariate probability that  $y_j$  is equal to the level `outcome()` and that  $y_j$  is not observed is calculated. When `outcome()` is not specified, the bivariate probabilities for each outcome level and no selection are calculated.

`pcond1` calculates the predicted probabilities of outcome levels conditional on selection.

You specify one or  $k$  new variables, where  $k$  is the number of categories of the outcome variable  $y_j$ . If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the probability that  $y_j$  is equal to the level `outcome()` given that  $y_j$  is observed is calculated. When `outcome()` is not specified, the probabilities for each outcome level conditional on selection are calculated.

`pcond0` calculates the predicted probabilities of outcome levels conditional on no selection.

You specify one or  $k$  new variables, where  $k$  is the number of categories of the outcome variable  $y_j$ . If you specify the `outcome()` option, you must specify one new variable. If you specify one new variable and do not specify `outcome()`, `outcome(#1)` is assumed.

When `outcome()` is specified, the probability that  $y_j$  is equal to the level `outcome()` given that  $y_j$  is not observed is calculated. When `outcome()` is not specified, the probabilities for each outcome level conditional on no selection are calculated.

`pse1` calculates the predicted univariate (marginal) probability of selection.

`xb` calculates the linear prediction for the outcome variable, which is  $\mathbf{x}_j\beta$  if `offset()` was not specified and  $\mathbf{x}_j\beta + \text{offset}_j^\beta$  if `offset()` was specified.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`xbse1` calculates the linear prediction for the selection equation, which is  $\mathbf{z}_j\boldsymbol{\gamma}$  if `offset()` was not specified in `select()` and  $\mathbf{z}_j\boldsymbol{\gamma} + \text{offset}_j$  if `offset()` was specified in `select()`.

`stdpse1` calculates the standard error of the linear prediction for the selection equation.

`outcome(outcome)` specifies for which outcome the predicted probabilities are to be calculated. `outcome()` should contain either one value of the dependent variable or one of #1, #2, ..., with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc.

`nooffset` is relevant only if you specified `offset(varname)` for `heckoprobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j\mathbf{b}$  rather than as  $\mathbf{x}_j\mathbf{b} + \text{offset}_j$ .

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$ .

When the dependent variable takes  $k$  different values, new variables three through  $k + 1$  will contain  $\partial \ln L / \partial (\kappa_{j-2})$ .

The last new variable will contain  $\partial \ln L / \partial (\text{atanh } \rho)$ .

## margins

### Description for margins

`margins` estimates margins of response for probabilities and linear predictions.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

*statistic*                      Description

---

| <code><u>x</u>b<u>s</u>el</code>   | linear prediction for selection equation            |
| <code>stdp</code>                  | not allowed with margins                            |
| <code><u>s</u>td<u>p</u>sel</code> | not allowed with margins                            |

---

`pmargin`, `p1`, `p0`, `pcond1`, and `pcond0` default to the first outcome.

Statistics not allowed with margins are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## Remarks and examples

### ▷ Example 1

In [example 1](#) of [\[R\] heckoprobit](#), we examined a simulated dataset of 5,000 women, 3,480 of whom work and can thus report job satisfaction. Using job satisfaction (`satisfaction`) as the outcome variable and employment (`work`) as the selection variable, we estimated the parameters of an ordered probit sample-selection model. Covariates `age` (`age`), years of education (`education`), number of children (`children`), and marital status (`married`) are expected to affect selection. The outcome, job satisfaction, is affected by `age` (`age`) and education (`education`).

We first reestimate the parameters of the regression, but this time we request a robust variance estimator:

```
. use https://www.stata-press.com/data/r19/womensat
(Job satisfaction, female)
. heckoprobit satisfaction education age,
> select(work=education age i.married#c.children) vce(robust)
(output omitted)
```

We then use `margins` (see [\[R\] margins](#)) to estimate the average marginal effect of education on the probability of having low job satisfaction.

```
. margins, dydx(education) vce(unconditional)
Average marginal effects Number of obs = 5,000
dy/dx wrt: education
1._predict: Pr(satisfaction=1), predict(pmargi outcome(1))
2._predict: Pr(satisfaction=2), predict(pmargi outcome(2))
3._predict: Pr(satisfaction=3), predict(pmargi outcome(3))
4._predict: Pr(satisfaction=4), predict(pmargi outcome(4))
```

|           | Unconditional |           |        |       |                       |
|-----------|---------------|-----------|--------|-------|-----------------------|
|           | dy/dx         | std. err. | z      | P> z  | [95% conf. interval]  |
| education |               |           |        |       |                       |
| _predict  |               |           |        |       |                       |
| 1         | -.0234776     | .0019176  | -12.24 | 0.000 | -.027236    -.0197192 |
| 2         | -.0230858     | .0015143  | -15.24 | 0.000 | -.0260538   -.0201178 |
| 3         | -.0020603     | .001142   | -1.80  | 0.071 | -.0042987    .000178  |
| 4         | .0486238      | .0018593  | 26.15  | 0.000 | .0449795    .052268   |

The estimated average marginal effect of education on the probability of having low job satisfaction is approximately  $-0.023$ .

## Methods and formulas

The ordinal outcome equation is

$$y_j = \sum_{h=1}^H v_h 1(\kappa_{h-1} < \mathbf{x}_j \boldsymbol{\beta} + u_{1j} \leq \kappa_h)$$

where  $\mathbf{x}_j$  is the outcome covariates,  $\boldsymbol{\beta}$  is the coefficients, and  $u_{1j}$  is a random-error term. The observed outcome values  $v_1, \dots, v_H$  are integers such that  $v_i < v_m$  for  $i < m$ .  $\kappa_1, \dots, \kappa_{H-1}$  are real numbers such that  $\kappa_i < \kappa_m$  for  $i < m$ .  $\kappa_0$  is taken as  $-\infty$  and  $\kappa_H$  is taken as  $+\infty$ .

The selection equation is

$$s_j = 1(\mathbf{z}_j \boldsymbol{\gamma} + u_{2j} > 0)$$

where  $s_j = 1$  if we observed  $y_j$  and 0 otherwise,  $\mathbf{z}_j$  is the covariates used to model the selection process,  $\boldsymbol{\gamma}$  is the coefficients for the selection process, and  $u_{2j}$  is a random-error term.

$(u_{1j}, u_{2j})$  have bivariate normal distribution with mean zero and variance matrix

$$\begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$$

The probability of selection is

$$\Pr(s_j = 1) = \Phi(\mathbf{z}_j \boldsymbol{\gamma} + \text{offset}_j^\gamma)$$

$\Phi(\cdot)$  is the standard cumulative normal distribution function.

The probability of selection and the outcome  $y_j = v_h$  is

$$\begin{aligned} \Pr(y_j = v_h, s_j = 1) &= \Phi_2(\mathbf{z}_j \boldsymbol{\gamma} + \text{offset}_j^\gamma, \kappa_h - x_j \boldsymbol{\beta} - \text{offset}_j^\beta, -\rho) \\ &\quad - \Phi_2(\mathbf{z}_j \boldsymbol{\gamma} + \text{offset}_j^\gamma, \kappa_{h-1} - \mathbf{x}_j \boldsymbol{\beta} - \text{offset}_j^\beta, -\rho) \end{aligned}$$

$\Phi_2(\cdot)$  is the cumulative bivariate normal distribution function (with mean  $[0 \ 0]'$ ).

The probability of  $y_j$  not being selected and the outcome  $y_j = v_h$  is

$$\begin{aligned} \Pr(y_j = v_h, s_j = 0) &= \Phi_2(-\mathbf{z}_j \boldsymbol{\gamma} - \text{offset}_j^\gamma, \kappa_h - x_j \boldsymbol{\beta} - \text{offset}_j^\beta, \rho) \\ &\quad - \Phi_2(-\mathbf{z}_j \boldsymbol{\gamma} - \text{offset}_j^\gamma, \kappa_{h-1} - \mathbf{x}_j \boldsymbol{\beta} - \text{offset}_j^\beta, \rho) \end{aligned}$$

The probability of outcome  $y_j = v_h$  given selection is

$$\Pr(y_j = v_h | s_j = 1) = \frac{\Pr(y_j = v_h, s_j = 1)}{\Pr(s_j = 1)}$$

The probability of outcome  $y_j = v_h$  given  $y_j$  is not selected is

$$\Pr(y_j = v_h | s_j = 0) = \frac{\Pr(y_j = v_h, s_j = 0)}{\Pr(s_j = 0)}$$

The marginal probabilities of the outcome  $y_j$  are

$$\Pr(y_j = v_1) = \Phi(\kappa_1 - x_j\beta - \text{offset}_j^\beta)$$

$$\Pr(y_j = v_H) = 1 - \Phi(\kappa_{H-1} - x_j\beta - \text{offset}_j^\beta)$$

$$\Pr(y_j = v_h) = \Phi(\kappa_h - x_j\beta - \text{offset}_j^\beta) - \Phi(\kappa_{h-1} - x_j\beta - \text{offset}_j^\beta)$$

## Description

`heckpoisson` fits a Poisson regression model with endogenous sample selection. This is sometimes called nonignorability of selection, missing not at random, or selection bias. Unlike the standard Poisson model, there is no assumption of equidispersion.

## Quick start

Poisson model of  $y$  on  $x_1$  with  $z_1$  predicting selection when binary variable `selected` indicates selection status

```
heckpoisson y x1, select(selected = z1)
```

Add categorical variable `a` using [factor-variables](#) syntax

```
heckpoisson y x1 i.a, select(selected = z1 i.a)
```

Report results as incidence-rate ratios

```
heckpoisson y x1 i.a, select(selected = z1 i.a) irr
```

Add robust standard errors

```
heckpoisson y x1 i.a, select(selected = z1 i.a) vce(robust)
```

Include exposure variable `expose` to account for different exposure levels

```
heckpoisson y x1 i.a, select(selected = z1 i.a) exposure(expose)
```

## Menu

Statistics > Sample-selection models > Poisson model with sample selection

## Syntax

```
heckpoisson depvar indepvars [if] [in] [weight] ,
 select([depvars =] indepvarss [, noconstant offset(varnameos)]) [options]
```

*options*

Description

### Model

\* select( )

specify selection equation: dependent and independent variables; whether to have constant term and offset variable

noconstant

suppress constant term

exposure(*varname*<sub>e</sub>)

include  $\ln(\text{varname}_e)$  in model with coefficient constrained to 1

offset(*varname*<sub>o</sub>)

include *varname*<sub>o</sub> in model with coefficient constrained to 1

constraints(*constraints*)

apply specified linear constraints

### SE/Robust

vce(*vcetype*)

*vcetype* may be oim, robust, cluster *clustvar*, opg, bootstrap, or jackknife

### Reporting

level(#)

set confidence level; default is level(95)

irr

report incidence-rate ratios

nocnsreport

do not display constraints

display\_options

control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

### Integration

intpoints(#)

set the number of integration (quadrature) points; default is intpoints(25)

### Maximization

maximize\_options

control the maximization process; seldom used

collinear

keep collinear variables

coeflegend

display legend instead of statistics

\* select( ) is required.

The full specification is select( [*depvar*<sub>s</sub> = ] *indepvars*<sub>s</sub> [ , noconstant offset(*varname*<sub>os</sub>) ] ).

*indepvars* and *indepvars*<sub>s</sub> may contain factor variables; see [U] 11.4.3 Factor variables.

*indepvars* and *indepvars*<sub>s</sub> may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bayesboot, bootstrap, by, collect, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce( ) and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`select([depvars = ] indepvarss [ , noconstant offset(varnameos) ])` specifies the variables and options for the selection equation. It is an integral part of specifying a sample-selection model and is required.

If *depvar*<sub>s</sub> is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If *depvar*<sub>s</sub> is not specified, then observations for which *depvar* is not missing are assumed selected and those for which *depvar* is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`offset`(*varname*<sub>os</sub>) specifies that selection offset *varname*<sub>os</sub> be included in the model with the coefficient constrained to be 1.

`noconstant`, `exposure`(*varname*<sub>e</sub>), `offset`(*varname*<sub>o</sub>), `constraints`(*constraints*); see [R] [Estimation options](#).

### SE/Robust

`vce`(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level`(#); see [R] [Estimation options](#).

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is,  $e^{\beta_i}$  rather than  $\beta_i$ . Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results.

`nocnsreport`; see [R] [Estimation options](#).

*display\_options*: `noci`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap`(#), `fvwrapon`(*style*), `cformat`(%*fmt*), `pformat`(%*fmt*), `sformat`(%*fmt*), and `nolstretch`; see [R] [Estimation options](#).

### Integration

`intpoints`(#) specifies the number of integration points to use for quadrature. The default is `intpoints`(25), which means that 25 quadrature points are used. The maximum number of allowed integration points is 128.

The more integration points, the more accurate the approximation to the log likelihood. However, computation time increases with the number of quadrature points and is roughly proportional to the number of points used.

Maximization

`maximize_options`: `difficult`, `technique` (`algorithm_spec`), `iterate`(#), `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance`(#), `ltolerance`(#), `nrtolerance`(#), `nonrtolerance`, and `from` (`init_specs`); see [R] [Maximize](#). These options are seldom used.

The following options are available with `heckpoisson` but are not shown in the dialog box: `collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

When analyzing observational data, we must consider the possibility that we cannot treat the observations for which we have data as if they were selected at random. Suppose we are interested in the number of after-school tutoring sessions a child attends. If unobservable variables that affect which students attend the sessions, for example, family stability, also affect the number of visits we observe, then a condition known as endogenous sample selection is present. This phenomenon is sometimes simply referred to as sample selection or called missing not at random, nonignorability of selection, or selection bias. When endogenous sample selection occurs, conventional estimation techniques are not appropriate. [Cameron and Trivedi \(2022, 974–981\)](#) and [Greene \(2018, 950–957\)](#) provide good introductions to the concept of endogenous sample selection.

The venerable Heckman estimator handles endogenous sample selection when the outcome of interest is modeled by linear regression; see [R] [heckman](#). However, the Heckman estimator is not appropriate for count outcomes because its linear model for the outcome could produce negative predicted values and does not restrict the predicted values to integers.

There are different methods for estimating the parameters of a count-data model with endogenous sample selection. `heckpoisson` implements the maximum likelihood estimator derived in [Terza \(1998\)](#); see also [Cameron and Trivedi \(2013, chap. 10\)](#) for a discussion of this estimator.

The model consists of one equation for the count outcome,  $y$ , and one equation for a binary selection indicator,  $s$ . The indicator  $s$  is always observed and takes values of 0 or 1. But the outcome  $y$  is observed only if  $s = 1$ , that is, we have complete information about the covariates of interest and selection status. However, the value of the primary outcome of interest,  $y$ , is sometimes unknown.

More formally, the count outcome  $y$  is assumed to have a Poisson distribution, conditional on the covariates, with conditional mean

$$E(y_j | \mathbf{x}_j, \epsilon_{1j}) = \exp(\mathbf{x}_j \boldsymbol{\beta} + \epsilon_{1j}) \quad \text{Poisson regression equation}$$

However, we only observe  $y$  for observation  $j$  if  $s_j = 1$ :

$$s_j = \begin{cases} 1, & \text{if } \mathbf{w}_j \boldsymbol{\gamma} + \epsilon_{2j} > 0 \\ 0, & \text{otherwise} \end{cases} \quad \text{selection equation}$$

where

$$\epsilon_1 \sim N(0, \sigma)$$

$$\epsilon_2 \sim N(0, 1)$$

$$\text{corr}(\epsilon_1, \epsilon_2) = \rho$$

When  $\rho \neq 0$ , standard Poisson regression based on the observed  $y$  yields biased estimates. `heckpoisson` provides consistent, asymptotically efficient estimates for the parameters in such models.

Unlike the standard Poisson regression, the Poisson model with sample selection allows underdispersion and overdispersion.

### ▷ Example 1: Poisson model with sample selection

Suppose we want to know the effect of research and development (R&D) expenditures on the number of patents obtained by a firm in the last two years. The patent dataset contains fictional data on the number of patents (`npatents`) of 10,000 firms in different sectors. After reading in the data, we tabulate the frequencies of `npatents` against an indicator for whether a firm applied for patents (`applied`).

```
. use https://www.stata-press.com/data/r19/patent
(Fictional data on patents and R&D)
. tabulate npatents applied, missing
```

| Number of<br>patents<br>(last 2<br>yrs) | Applied for patent |       | Total  |
|-----------------------------------------|--------------------|-------|--------|
|                                         | Not apply          | Apply |        |
| 0                                       | 0                  | 1,127 | 1,127  |
| 1                                       | 0                  | 1,455 | 1,455  |
| 2                                       | 0                  | 1,131 | 1,131  |
| 3                                       | 0                  | 710   | 710    |
| 4                                       | 0                  | 479   | 479    |
| 5                                       | 0                  | 266   | 266    |
| 6                                       | 0                  | 126   | 126    |
| 7                                       | 0                  | 98    | 98     |
| 8                                       | 0                  | 66    | 66     |
| 9                                       | 0                  | 42    | 42     |
| 10                                      | 0                  | 19    | 19     |
| 11                                      | 0                  | 24    | 24     |
| 12                                      | 0                  | 5     | 5      |
| 13                                      | 0                  | 7     | 7      |
| 14                                      | 0                  | 5     | 5      |
| 15                                      | 0                  | 10    | 10     |
| 17                                      | 0                  | 1     | 1      |
| 18                                      | 0                  | 1     | 1      |
| 19                                      | 0                  | 2     | 2      |
| 22                                      | 0                  | 1     | 1      |
| .                                       | 4,425              | 0     | 4,425  |
| Total                                   | 4,425              | 5,575 | 10,000 |

The output shows that `npatents` is missing for about half of the sample because some firms did not apply for any patents. Some firms prefer to keep their discoveries as trade secrets instead of applying for patents. The sample selection will be endogenous if the unobservable variables that affect which firms apply for patents also affect the number of patents obtained. Therefore, we do not want to use a standard Poisson model for these data.

We model `npatents` as a function of R&D expenditures (`expenditure`) and a categorical variable indicating whether the firm is in the information technology (IT) sector (`tech`). We model the selection indicator `applied` as a function of `expenditure`, `tech`, and firm size (`size`), which is excluded from the outcome model.

```
. heckpoisson npatents expenditure i.tech,
> select(applied = expenditure size i.tech)
Initial: Log likelihood = -17442.266

| sigma       | .7386224    | .036907   |       |       | .6697151             | .8146195  |

Wald test of indep. eqns. (rho = 0): chi2(1) = 16.64 Prob > chi2 = 0.0000

The coefficient estimates reported by `heckpoisson` can be interpreted similarly to those reported by `poisson`. For example, the positive coefficient on `expenditure` tells us that increasing R&D expenditures is associated with an increasing number of patents. However, the magnitude of the effect cannot be directly determined by the coefficients. The best way to obtain interpretable effects is by using `margins`. See [example 1](#) in [R] `heckpoisson postestimation` for more information.

The estimated correlation between the selection errors and outcome errors is 0.8, and the Wald test in the footer indicates that we can reject the null hypothesis of zero correlation. This positive and significant correlation estimate implies that unobservable factors that increase the number of patents a firm is awarded tend to occur with unobservable factors that also increase the chance of a firm being willing to apply for patents.

□ Technical note

In practice, we rely on the strength of the relationship between size and applied and the fact that size does not appear in the model for npatents to pin down the parameter estimates. Technically, we do not need this exclusion restriction, but identification from the functional form alone tends to be weak. For a discussion of this point, see [Cameron and Trivedi \(2022, 977–981\)](#). □

▷ Example 2: Obtaining incidence-rate ratios

In some cases, we may wish to view the parameters as incidence-rate ratios (IRRs). That is, we want to hold all the  $x$ 's in the model constant except one, say, the  $i$ th. The IRR for a one-unit change in  $x_i$  is

$$\frac{e^{\ln(E)+\beta_1x_1+\dots+\beta_i(x_i+1)+\dots+\beta_kx_k+e_1}}{e^{\ln(E)+\beta_1x_1+\dots+\beta_ix_i+\dots+\beta_kx_k+e_1}} = e^{\beta_i}$$

For instance, we may want to know the relative incidence rate of patents as the expenditure changes or the relative incidence rate of patents as sectors change from non-IT to IT.

We can use option `irr` to display the coefficient estimates transformed to IRRs. This option may be specified when we originally fit our model or on replay. Because we have already fit the model, we specify `irr` below using the replay syntax.

```
. heckpoisson, irr
Poisson regression with endogenous selection Number of obs = 10,000
(25 quadrature points) Selected = 5,575
 Nonselected = 4,425
 Wald chi2(2) = 443.90
Log likelihood = -17440.44 Prob > chi2 = 0.0000
```

| npatents    | IRR       | Std. err. | z     | P> z  | [95% conf. interval] |           |
|-------------|-----------|-----------|-------|-------|----------------------|-----------|
| npatents    |           |           |       |       |                      |           |
| expenditure | 1.645133  | .0835508  | 9.80  | 0.000 | 1.489262             | 1.817316  |

| rho         | .8215857  | .0925557  |       |       | .5395353             | .9378455  |
| sigma       | .7386224  | .036907   |       |       | .6697151             | .8146195  |

Note: Estimates are transformed only in the first equation to incidence-rate ratios.

Note: `_cons` estimates baseline incidence rate.

Wald test of indep. eqns. (rho = 0): chi2(1) = 16.64 Prob > chi2 = 0.0000

The IRR for IT is about 1.8, meaning that the expected number of patents in the IT sector is 1.8 times more than in the non-IT sector.

## Stored results

heckpoisson stores the following in `e()`:

## Matrices

|                 |                                              |
|-----------------|----------------------------------------------|
| e(b)            | coefficient vector                           |
| e(Cns)          | constraints matrix                           |
| e(iLog)         | iteration log (up to 20 iterations)          |
| e(gradient)     | gradient vector                              |
| e(V)            | variance–covariance matrix of the estimators |
| e(V_modelbased) | model-based variance                         |

## Functions

|           |                         |
|-----------|-------------------------|
| e(sample) | marks estimation sample |
|-----------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|          |                                                                                                                       |
|----------|-----------------------------------------------------------------------------------------------------------------------|
| r(table) | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |
|----------|-----------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

`heckpoisson` implements [Terza's](#) maximum likelihood estimator for the parameters of a count-data model with endogenous sample selection ([Terza 1998](#)).

Suppose that the count outcome  $y_j$  has covariates  $\mathbf{x}_j$  and that  $y_j$  has a Poisson distribution, conditional on  $\mathbf{x}_j$ , with conditional mean

$$E(y_j | \mathbf{x}_j, \epsilon_{1j}) = \mu_j = \exp(\mathbf{x}_j \boldsymbol{\beta} + \epsilon_{1j})$$

and

$$\Pr(Y = y_j | \mathbf{x}_j, \epsilon_{1j}) = \frac{\mu_j^{y_j} e^{-\mu_j}}{y_j!}$$

We only observe  $y_j$  when  $s_j$ , the selection outcome, which is the binary outcome from a latent-variable model with covariates  $\mathbf{w}_j$ , is equal to 1.

$$s_j = \begin{cases} 1, & \text{if } \mathbf{w}_j \boldsymbol{\gamma} + \epsilon_{2j} > 0 \\ 0, & \text{otherwise} \end{cases}$$

The error terms  $\epsilon_1$  and  $\epsilon_2$  are assumed to have bivariate normal distribution with zero mean and covariance matrix

$$\begin{bmatrix} \sigma^2 & \sigma\rho \\ \sigma\rho & 1 \end{bmatrix}$$

where  $\sigma$  and  $\rho$  have their usual interpretation for the bivariate normal distribution. A nonzero  $\rho$  implies that the selected sample is not representative of the whole population and therefore that inference based on standard Poisson regression using the observed sample is incorrect.

In maximum likelihood estimation,  $\ln \sigma$  and  $\operatorname{atanh} \rho$  are estimated rather than directly estimating  $\sigma$  and  $\rho$ .

$$\operatorname{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

The joint log likelihood is given by

$$\ln L(\boldsymbol{\theta}) = \sum_{i=1}^N [s_j \times \ln\{\Pr(y_j, s_j = 1 | \mathbf{x}_j, \mathbf{w}_j, \boldsymbol{\theta})\} + (1 - s_j) \times \ln\{\Pr(s_j = 0 | \mathbf{w}_j, \boldsymbol{\theta})\}]$$

where  $\boldsymbol{\theta}$  denotes  $(\beta, \gamma, \rho, \sigma)$  for notational simplicity.

The joint probability  $\Pr(y_j, s_j = 1 | \mathbf{x}_j, \mathbf{w}_j, \boldsymbol{\theta})$  can be obtained by integrating the conditional probability  $\Pr(y_j, s_j = 1 | \mathbf{x}_j, \mathbf{w}_j, \boldsymbol{\theta}, \epsilon_1)$  over  $\epsilon_1$ . More precisely,

$$\Pr(y_j, s_j = 1 | \mathbf{x}_j, \mathbf{w}_j, \boldsymbol{\theta}) = \int_{-\infty}^{\infty} \Pr(y_j | \mathbf{x}_j, \epsilon_1) \Phi\left(\frac{\mathbf{w}_j \gamma + \rho / \sigma \epsilon_1}{\sqrt{1 - \rho^2}}\right) \phi(\epsilon_1 / \sigma) d\epsilon_1 \quad (1)$$

where  $\phi(\cdot)$  is the standard normal density function and  $\Phi(\cdot)$  is the standard normal cumulative density function.  $\Pr(s_j = 0 | \mathbf{w}_j, \boldsymbol{\theta})$  is similarly derived.

$$\Pr(s_j = 0 | \mathbf{w}_j, \boldsymbol{\theta}) = \int_{-\infty}^{\infty} \Phi\left(-\frac{\mathbf{w}_j \gamma + \rho / \sigma \epsilon_1}{\sqrt{1 - \rho^2}}\right) \phi(\epsilon_1 / \sigma) d\epsilon_1 \quad (2)$$

The integrations in (1) and (2) have no closed form and must be approximated using Gauss–Hermite quadrature.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] [\\_robust](#), particularly *Maximum likelihood estimators* and *Methods and formulas*.

`heckpoisson` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

## Postestimation commands

The following postestimation commands are available after `heckpoisson`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from <code>margins</code> (profile plots, interaction plots, etc.)                                                    |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | number of events, incidence rates, probabilities, etc.                                                                                  |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.

## predict

### Description for predict

`predict` creates new variables containing predictions such as number of events, incidence rates, conditional predicted number of events, probabilities, linear predictions, and equation-level scores.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] stub* [if] [in], scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

| <i>statistic</i>     | Description                                                    |
|----------------------|----------------------------------------------------------------|
| Main                 |                                                                |
| <code>n</code>       | number of events; the default                                  |
| <code>ir</code>      | incidence rate                                                 |
| <code>ncond</code>   | predicted number of events conditional on $y_j$ being observed |
| <code>pr(n)</code>   | $\Pr(y_j = n)$                                                 |
| <code>pr(a,b)</code> | $\Pr(a \leq y_j \leq b)$                                       |
| <code>pse1</code>    | $\Pr(y_j \text{ observed})$                                    |
| <code>xb</code>      | linear prediction                                              |
| <code>xbse1</code>   | linear prediction for selection equation                       |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

### Options for predict

Main

`n`, the default, calculates the predicted number of events, which is  $\exp(\mathbf{x}_j\beta + \sigma^2/2)$  if neither `offset()` nor `exposure()` was specified when the model was fit; is  $\exp(\mathbf{x}_j\beta + \sigma^2/2 + \text{offset}_j)$  if `offset()` was specified; or is  $\exp(\mathbf{x}_j\beta + \sigma^2/2) \times \text{exposure}_i$  if `exposure()` was specified.

`ir` calculates the incidence rate  $\exp(\mathbf{x}_j\beta + \sigma^2/2)$ , which is the predicted number of events when exposure is 1. Specifying `ir` is equivalent to specifying `n` when neither `offset()` nor `exposure()` was specified when the model was fit.

`ncond` calculates the predicted number of events conditional on  $y_j$  being observed, which is  $\exp(\mathbf{x}_j\beta + \sigma^2/2)\Phi(\mathbf{w}_j\gamma + \rho\sigma)/\Phi(\mathbf{w}_j\gamma)$ .

`pr(n)` calculates the probability  $\Pr(y_j = n)$ , where  $n$  is a nonnegative integer that may be specified as a number or a variable.

`pr(a, b)` calculates the probability  $\Pr(a \leq y_j \leq b)$ , where  $a$  and  $b$  are nonnegative integers that may be specified as numbers or variables;

$b$  missing ( $b \geq .$ ) means  $+\infty$ ;

`pr(20, .)` calculates  $\Pr(y_j \geq 20)$ ;

`pr(20, b)` calculates  $\Pr(y_j \geq 20)$  in observations for which  $b \geq .$  and calculates  $\Pr(20 \leq y_j \leq b)$  elsewhere.

`pr(., b)` produces a syntax error. A missing value in an observation of the variable  $a$  causes a missing value in that observation for `pr(a, b)`.

`pselect` calculates the probability of selection (or being observed):

$$\Pr(y_j \text{ observed}) = \Pr(\mathbf{w}_j\gamma + \epsilon_{2j} > 0)$$

`xb` calculates the linear prediction for the dependent count variable, which is  $\mathbf{x}_j\beta$  if neither `offset()` nor `exposure()` was specified;  $\mathbf{x}_j\beta + \text{offset}_j^\beta$  if `offset()` was specified; or  $\mathbf{x}_j\beta + \ln(\text{exposure}_j)$  if `exposure()` was specified.

`xbselect` calculates the linear prediction for the selection equation, which is  $\mathbf{w}_j\gamma$  if `offset()` was not specified in `select()` and is  $\mathbf{w}_j\gamma + \text{offset}_j^\gamma$  if `offset()` was specified in `select()`.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable; the linear prediction is treated as  $\mathbf{x}_j\beta$  rather than as  $\mathbf{x}_j\beta + \text{offset}_j$  or  $\mathbf{x}_j\beta + \ln(\text{exposure}_j)$ .

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\beta)$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{w}_j\gamma)$ .

The third new variable will contain  $\partial \ln L / \partial \text{atanh } \rho$ .

The fourth new variable will contain  $\partial \ln L / \partial \ln \sigma$ .

# margins

## Description for margins

`margins` estimates margins of response for number of events, incidence rates, conditional predicted number of events, probabilities, and linear predictions.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>                    | Description                                                    |
|-------------------------------------|----------------------------------------------------------------|
| <code>n</code>                      | number of events; the default                                  |
| <code>ir</code>                     | incidence rate                                                 |
| <code>ncond</code>                  | predicted number of events conditional on $y_j$ being observed |
| <code>pr(<i>n</i>)</code>           | $\Pr(y_j = n)$                                                 |
| <code>pr(<i>a</i>, <i>b</i>)</code> | $\Pr(a \leq y_j \leq b)$                                       |
| <code>pselect</code>                | $\Pr(y_j \text{ observed})$                                    |
| <code>xb</code>                     | linear prediction                                              |
| <code>xbselect</code>               | linear prediction for selection equation                       |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## Remarks and examples

### ► Example 1: Obtaining margins for a count model with selection

In [example 1](#) of [R] [heckpoisson](#), we fit a model for the number of patents. In that example, we are interested in the effect of R&D expenditures on the number of patents received by a firm. We continue that example to determine the magnitude of the effect of R&D expenditures on the number of patents and compare this effect for IT and non-IT sectors.

After reading in the data and fitting the model, we use `margins` to estimate the effect of an increase of a million dollars in R&D expenditures (`expenditure`) on the number of patents (`npatents`) for firms in the IT and non-IT sectors (`tech`).

To do this, we use the `at()` option of `margins`. We use the observed values in our first scenario, so we tell `margins` to set `expenditure` equal to itself. For our second scenario, we tell `margins` to set `expenditure` equal to the observed value plus 1 because expenditures are measured in millions of dollars. We include the `post` option so that we can perform additional calculations later.

```
. use https://www.stata-press.com/data/r19/patent
(Fictional data on patents and R&D)
. quietly heckpoisson npatents expenditure i.tech,
> select(applied = expenditure size i.tech)
. margins i.tech, at(expenditure = generate(expenditure))
> at(expenditure = generate(expenditure+1)) post
Predictive margins Number of obs = 10,000
Model VCE: OIM
Expression: Predicted number of events, predict()
1._at: expenditure = expenditure
2._at: expenditure = expenditure+1
```

|             | Delta-method |           |       |       | [95% conf. interval] |          |

| Non-IT se.. | 1.276213     | .0556644  | 22.93 | 0.000 | 1.167112             | 1.385313 |
| 1#IT sector | 2.287013     | .080119   | 28.55 | 0.000 | 2.129983             | 2.444044 |
| 2 #         |              |           |       |       |                      |          |
| Non-IT se.. | 2.099539     | .131364   | 15.98 | 0.000 | 1.84207              | 2.357007 |
| 2#IT sector | 3.76244      | .2226221  | 16.90 | 0.000 | 3.326109             | 4.198771 |

The output indicates that the expected number of patents for non-IT firms is about 1.28 compared with 2.29 for firms in the IT sector.

The second scenario shows the expected number of patents after our hypothetical increase in R&D expenditures. In the non-IT sector, the expected number of patents received would be about 2.10 compared with 3.76 in the IT sector. It appears that increasing expenditures may have a larger effect for IT firms—the difference between the two scenarios is 1.47 for IT firms and only 0.82 for non-IT firms. We can test whether the effect of increasing expenditures is different for IT and non-IT firms. We use `lincom` to obtain an estimate of the difference in the differences between scenarios for the two sectors and a test of its significance. We ask for the differences by referring to the scenarios as 1.\_at and 2.\_at and by referring to the sector using the value that corresponds to the IT sector indicator, 1.tech for IT firms and 0.tech otherwise.

```
. lincom (_b[2._at#1.tech] - _b[1._at#1.tech]) -
> (_b[2._at#0.tech] - _b[1._at#0.tech])
(1) 1bn._at#0bn.tech - 1bn._at#1.tech - 2._at#0bn.tech + 2._at#1.tech = 0
```

|     | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|-------------|-----------|------|-------|----------------------|----------|
| (1) | .6521006    | .0917299  | 7.11 | 0.000 | .4723134             | .8318878 |

We find that the expected effect of increasing R&D expenditures by one million dollars is 0.65 patents larger for IT firms than for non-IT firms, and this difference is significantly different from 0.

## Methods and formulas

Suppose that the count outcome  $y_j$  has covariates  $\mathbf{x}_j$  and the selection outcome  $s_j$  has covariates  $\mathbf{w}_j$ .  $y_j$  is assumed to have a Poisson distribution, conditional on  $\mathbf{x}_j$ , with conditional mean

$$E(y_j|\mathbf{x}_j, \epsilon_{1j}) = \mu_j = \exp(\mathbf{x}_j\boldsymbol{\beta} + \epsilon_{1j})$$

$s_j$  is a binary outcome from a latent-variable model:

$$s_j = \begin{cases} 1, & \text{if } \mathbf{w}_j\boldsymbol{\gamma} + \epsilon_{2j} > 0 \\ 0, & \text{otherwise} \end{cases}$$

The expectation of  $y_j$  conditional on covariates  $\mathbf{x}_j$  for the whole population is

$$E(y_j|\mathbf{x}_j) = \exp(\mathbf{x}_j\boldsymbol{\beta} + \sigma^2/2)$$

Furthermore, if we want the expectation of  $y_j$  only if it was observed, then the formula is

$$E(y_j|\mathbf{x}_j, \mathbf{w}_j, s_j = 1) = \exp(\mathbf{x}_j\boldsymbol{\beta} + \sigma^2/2) \frac{\Phi(\mathbf{w}_j\boldsymbol{\gamma} + \rho\sigma)}{\Phi(\mathbf{w}_j\boldsymbol{\gamma})}$$

We note that if  $\rho = 0$ , this expectation is the same as its population version.

We can also predict the probability of  $y_j$  conditional on  $\mathbf{x}_j$ . Note that although  $y_j$  is Poisson-distributed conditional on  $\epsilon_1$  and  $\mathbf{x}_j$ , the distribution of  $y_j$  is unknown unconditional on  $\epsilon_1$ .

$$\Pr(y_j = n|\mathbf{x}_j) = \int_{-\infty}^{\infty} \Pr(y_j = n|\mathbf{x}_j, \epsilon_1) \phi(\epsilon_1/\sigma) d\epsilon_1$$

As in the implementation of log likelihood, we approximate this integral by Gauss–Hermite quadrature.

## Description

`heckprobit` fits maximum-likelihood probit models with sample selection.

## Quick start

Probit model of  $y$  on  $x$  with sample selection indicated by binary variable `selected` and predicted by  $v$

```
heckprobit y x, select(selected = v x)
```

Suppress iteration log

```
heckprobit y x, select(selected = v x) nolog
```

With cluster-robust standard errors for clustering by levels of `cvar`

```
heckprobit y x, select(selected = v x) vce(cluster cvar)
```

## Menu

Statistics > Sample-selection models > Probit model with sample selection

## Syntax

```
heckprobit depvar indepvars [if] [in] [weight],
 select([depvars =] varlists [, noconstant offset(varnameo)]) [options]
```

| <u>display_options</u>                    | control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling |
| <b>Maximization</b>                       |                                                                                                                                                  |
| <u>maximize_options</u>                   | control the maximization process; seldom used                                                                                                    |
| <u>collinear</u>                          | keep collinear variables                                                                                                                         |
| <u>coeflegend</u>                         | display legend instead of statistics                                                                                                             |

\*select() is required.

The full specification is `select([depvars = ] varlists [ , noconstant offset(varnameo) ])`.

*indepvars* and *varlist*<sub>s</sub> may contain factor variables; see [U] 11.4.3 Factor variables.

*depvar*, *indepvars*, *depvar*<sub>s</sub>, and *varlist*<sub>s</sub> may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bayes, bayesboot, bootstrap, by, collect, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: heckprobit.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce(), first, lrmodel, and weights are not allowed with the svy prefix; see [SVY] svy.

pweights, fweights, and iweights are allowed; see [U] 11.1.6 weight.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`select( [ depvars = ] varlists [ , noconstant offset(varnameo) ] )` specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If *depvar*<sub>s</sub> is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If *depvar*<sub>s</sub> is not specified, observations for which *depvar* is not missing are assumed selected, and those for which *depvar* is missing are assumed not selected.

`noconstant` suppresses the selection constant term (intercept).

`offset(varnameo)` specifies that selection offset *varname*<sub>o</sub> be included in the model with the coefficient constrained to be 1.

`noconstant`, `offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`first` specifies that the first-step probit estimates of the selection equation be displayed before estimation.

`lrmodel`, `nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default *vcetype* to `vce(opg)`.

The following options are available with `heckprobit` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

The probit model with sample selection (Van de Ven and Van Pragg 1981) assumes that there exists an underlying relationship

$$y_j^* = \mathbf{x}_j\boldsymbol{\beta} + u_{1j} \quad \textit{latent equation}$$

such that we observe only the binary outcome

$$y_j^{\text{probit}} = (y_j^* > 0) \quad \textit{probit equation}$$

The dependent variable, however, is not always observed. Rather, the dependent variable for observation  $j$  is observed if

$$y_j^{\text{select}} = (\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0) \quad \textit{selection equation}$$

where

$$u_1 \sim N(0, 1)$$

$$u_2 \sim N(0, 1)$$

$$\text{corr}(u_1, u_2) = \rho$$

When  $\rho \neq 0$ , standard probit techniques applied to the first equation yield biased results. `heckprobit` provides consistent, asymptotically efficient estimates for all the parameters in such models.

For the model to be well identified, the selection equation should have at least one variable that is not in the probit equation. Otherwise, the model is identified only by functional form, and the coefficients have no structural interpretation.

### ▷ Example 1

We use the data from Pindyck and Rubinfeld (1998). In this dataset, the variables are whether children attend private school (`private`), number of years the family has been at the present residence (`years`), log of property tax (`logptax`), log of income (`loginc`), and whether one voted for an increase in property taxes (`vote`).

In this example, we alter the meaning of the data. Here we assume that we observe whether children attend private school only if the family votes for increasing the property taxes. This assumption is not true in the dataset, and we make it only to illustrate the use of this command.

We observe whether children attend private school only if the head of household voted for an increase in property taxes. We assume that the vote is affected by the number of years in residence, the current property taxes paid, and the household income. We wish to model whether children are sent to private school on the basis of the number of years spent in the current residence and the current property taxes paid.

```

| rho            | -.6994978   | .7405281  |       |       | -.9987983            | .9622674  |

LR test of indep. eqns. (rho = 0): chi2(1) = 0.27      Prob > chi2 = 0.6020

The output shows several iteration logs. The first iteration log corresponds to running the probit model for those observations in the sample where we have observed the outcome. The second iteration log corresponds to running the selection probit model, which models whether we observe our outcome of interest. If  $\rho = 0$ , the sum of the log likelihoods from these two models will equal the log likelihood of the probit model with sample selection; this sum is printed in the iteration log as the comparison log likelihood. The third iteration log shows starting values for the iterations.

The final iteration log is for fitting the full probit model with sample selection. A likelihood-ratio test of the log likelihood for this model and the comparison log likelihood is presented at the end of the output. If we had specified the `vce(robust)` option, this test would be presented as a Wald test instead of as a likelihood-ratio test.

◀

## ▷ Example 2

In [example 1](#), we could have obtained robust standard errors by specifying the `vce(robust)` option. We do this here and also eliminate the iteration logs by using the `noolog` option:

```
. heckprobit private years logptax, sel(vote=years loginc logptax) vce(robust)
> noolog
Probit model with sample selection Number of obs = 95
 Selected = 59
 Nonselected = 36
 Wald chi2(2) = 2.55
 Prob > chi2 = 0.2798
Log pseudolikelihood = -74.24497
```

|         | Robust      |           | z     | P> z  | [95% conf. interval] |           |
|---------|-------------|-----------|-------|-------|----------------------|-----------|
|         | Coefficient | std. err. |       |       |                      |           |

```
Wald test of indep. eqns. (rho = 0): chi2(1) = 0.28 Prob > chi2 = 0.5952
```

Regardless of whether we specify the `vce(robust)` option, the outcome is not significantly different from the outcome obtained by fitting the probit and selection models separately. This result is not surprising because the selection mechanism estimated was invented for the example rather than borne from any economic theory.

◀

## Stored results

heckprobit stores the following in `e()`:

### Scalars

|                               |                                           |
|-------------------------------|-------------------------------------------|
| <code>e(N)</code>             | number of observations                    |
| <code>e(N_selected)</code>    | number of selected observations           |
| <code>e(N_nonselected)</code> | number of nonselected observations        |
| <code>e(k)</code>             | number of parameters                      |
| <code>e(k_eq)</code>          | number of equations in <code>e(b)</code>  |
| <code>e(k_eq_model)</code>    | number of equations in overall model test |
| <code>e(k_aux)</code>         | number of auxiliary parameters            |
| <code>e(k_dv)</code>          | number of dependent variables             |
| <code>e(df_m)</code>          | model degrees of freedom                  |
| <code>e(ll)</code>            | log likelihood                            |

| <code>e(Cns)</code>          | constraints matrix                           |
| <code>e(ilog)</code>         | iteration log (up to 20 iterations)          |
| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(V)</code>            | variance-covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

Functions  
`e(sample)` marks estimation sample

In addition to the above, the following is stored in `r()`:

Matrices  
`r(table)` matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Van de Ven and Van Pragg (1981) provide an introduction and an explanation of this model.

The probit equation is

$$y_j = (\mathbf{x}_j\boldsymbol{\beta} + u_{1j} > 0)$$

The selection equation is

$$\mathbf{z}_j\boldsymbol{\gamma} + u_{2j} > 0$$

where

$$u_1 \sim N(0, 1)$$

$$u_2 \sim N(0, 1)$$

$$\text{corr}(u_1, u_2) = \rho$$

The log likelihood is

$$\begin{aligned} \ln L = & \sum_{\substack{j \in S \\ y_j \neq 0}} w_j \ln \left\{ \Phi_2 \left( x_j\boldsymbol{\beta} + \text{offset}_j^\beta, z_j\boldsymbol{\gamma} + \text{offset}_j^\gamma, \rho \right) \right\} \\ & + \sum_{\substack{j \in S \\ y_j = 0}} w_j \ln \left\{ \Phi_2 \left( -x_j\boldsymbol{\beta} + \text{offset}_j^\beta, z_j\boldsymbol{\gamma} + \text{offset}_j^\gamma, -\rho \right) \right\} \\ & + \sum_{j \notin S} w_j \ln \left\{ 1 - \Phi \left( z_j\boldsymbol{\gamma} + \text{offset}_j^\gamma \right) \right\} \end{aligned}$$

where  $S$  is the set of observations for which  $y_j$  is observed,  $\Phi_2(\cdot)$  is the cumulative bivariate normal distribution function (with mean  $[0 \ 0]'$ ),  $\Phi(\cdot)$  is the standard cumulative normal, and  $w_j$  is an optional weight for observation  $j$ .

In the maximum likelihood estimation,  $\rho$  is not directly estimated. Directly estimated is  $\text{atanh } \rho$ :

$$\text{atanh } \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

From the form of the likelihood, it is clear that if  $\rho = 0$ , the log likelihood for the probit model with sample selection is equal to the sum of the probit model for the outcome  $y$  and the selection model. We can perform a likelihood-ratio test by comparing the likelihood of the full model with the sum of the log likelihoods for the probit and selection models.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] [\\_robust](#), particularly *Maximum likelihood estimators* and *Methods and formulas*.

`heckprobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

## Postestimation commands

The following postestimation commands are available after `heckprobit`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | probabilities, linear predictions and their SEs, etc.                                                                                   |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`hausman` and `lrtest` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as probabilities, linear predictions, and standard errors.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i>         | Description                                                                                                                                      |
|--------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|

| <u>x</u> b <u>s</u> el   | linear prediction for selection equation                                                                                                         |
| <u>s</u> td <u>p</u> sel | standard error of the linear prediction for selection equation                                                                                   |

$\Phi(\cdot)$  is the standard normal distribution function, and  $\Phi_2(\cdot)$  is the bivariate normal distribution function.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`pmargin`, the default, calculates the univariate (marginal) predicted probability of success

$$\Pr(y_j^{\text{probit}} = 1).$$

`p11` calculates the bivariate predicted probability  $\Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 1)$ .

`p10` calculates the bivariate predicted probability  $\Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 0)$ .

`p01` calculates the bivariate predicted probability  $\Pr(y_j^{\text{probit}} = 0, y_j^{\text{select}} = 1)$ .

`p00` calculates the bivariate predicted probability  $\Pr(y_j^{\text{probit}} = 0, y_j^{\text{select}} = 0)$ .

`pse1` calculates the univariate (marginal) predicted probability of selection  $\Pr(y_j^{\text{select}} = 1)$ .

`pcond` calculates the conditional (on selection) predicted probability of success

$$\Pr(y_j^{\text{probit}} = 1, y_j^{\text{select}} = 1) / \Pr(y_j^{\text{select}} = 1).$$

`xb` calculates the probit linear prediction  $\mathbf{x}_j\mathbf{b}$ .

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`xbse1` calculates the linear prediction for the selection equation.

`stdpse1` calculates the standard error of the linear prediction for the selection equation.

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$ .

The third new variable will contain  $\partial \ln L / \partial (\text{atanh } \rho)$ .

`nooffset` is relevant only if you specified `offset` (*varname*) for `heckprobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j\mathbf{b}$  rather than as  $\mathbf{x}_j\mathbf{b} + \text{offset}_j$ .

# margins

## Description for margins

margins estimates margins of response for probabilities and linear predictions.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>      | Description                                                                                                                                      |
|-----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------|

| stdp                  | not allowed with margins                                                                                                                         |
| std <u>p</u> sel      | not allowed with margins                                                                                                                         |

Statistics not allowed with margins are functions of stochastic quantities other than  $\mathbf{e}(\mathbf{b})$ .

For the full syntax, see [\[R\] margins](#).

## Remarks and examples

### ▷ Example 1

It is instructive to compare the marginal predicted probabilities with the predicted probabilities that we would obtain by ignoring the selection mechanism. To compare the two approaches, we will synthesize data so that we know the “true” predicted probabilities.

First, we need to generate correlated error terms, which we can do using a standard Cholesky decomposition approach. For our example, we will clear any data from memory and then generate errors that have a correlation of 0.5 by using the following commands. We set the seed so that interested readers can type in these same commands and obtain the same results.

```
. set seed 12309
. set obs 5000
Number of observations (_N) was 0, now 5,000.
. generate c1 = rnormal()
. generate c2 = rnormal()
. matrix P = (1, .5 \ .5, 1)
. matrix A = cholesky(P)
. local fac1 = A[2,1]
. local fac2 = A[2,2]
. generate u1 = c1
. generate u2 = 'fac1'*c1 + 'fac2'*c2
```

We can check that the errors have the correct correlation by using the `correlate` command. We will also normalize the errors so that they have a standard deviation of one, so we can generate a bivariate probit model with known coefficients. We do that with the following commands:

```
. correlate u1 u2
(obs=5,000)
```

|    | u1     | u2     |
|----|--------|--------|
| u1 | 1.0000 |        |
| u2 | 0.5012 | 1.0000 |

```
. summarize u1
(output omitted)
. replace u1 = u1/r(sd)
(5,000 real changes made)
. summarize u2
(output omitted)
. replace u2 = u2/r(sd)
(5,000 real changes made)
. drop c1 c2
. generate x1 = runiform()-.5
. generate x2 = runiform()+1/3
. generate y1s = 0.5 + 4*x1 + u1
. generate y2s = 3 - 3*x2 + .5*x1 + u2
. generate y1 = (y1s>0)
. generate y2 = (y2s>0)
```

We have now created two dependent variables,  $y_1$  and  $y_2$ , which are defined by our specified coefficients. We also included error terms for each equation, and the error terms are correlated. We run `heckprobit` to verify that the data have been correctly generated according to the model

$$y_1 = 0.5 + 4x_1 + u_1$$

$$y_2 = 3 + 0.5x_1 - 3x_2 + u_2$$

where we assume that  $y_1$  is observed only if  $y_2 = 1$ .

```
. heckprobit y1 x1, sel(y2 = x1 x2) nolog
Probit model with sample selection Number of obs = 5,000
 Selected = 3,182
 Nonselected = 1,818
 Wald chi2(1) = 947.76
 Prob > chi2 = 0.0000
Log likelihood = -3612.401
```

|           | Coefficient | Std. err. | z      | P> z  | [95% conf. interval] |           |
|-----------|-------------|-----------|--------|-------|----------------------|-----------|
| <b>y1</b> |             |           |        |       |                      |           |
| x1        | 4.015564    | .130436   | 30.79  | 0.000 | 3.759914             | 4.271214  |
| _cons     | .4795158    | .0471276  | 10.17  | 0.000 | .3871473             | .5718842  |
| <b>y2</b> |             |           |        |       |                      |           |
| x1        | .5361114    | .0711951  | 7.53   | 0.000 | .3965715             | .6756513  |
| x2        | -3.017537   | .0817541  | -36.91 | 0.000 | -3.177772            | -2.857302 |
| _cons     | 2.990145    | .0765942  | 39.04  | 0.000 | 2.840024             | 3.140267  |
| /athrho   | .5339516    | .0854577  | 6.25   | 0.000 | .3664575             | .7014457  |
| rho       | .4883959    | .0650735  |        |       | .3508892             | .6052846  |

```
LR test of indep. eqns. (rho = 0): chi2(1) = 41.36 Prob > chi2 = 0.0000
```

Now that we have verified that we have generated data according to a known model, we can obtain and then compare predicted probabilities from the probit model with sample selection and a (usual) probit model.

```
. predict pmarg
(option pmargin assumed; Pr(y1=1))
. probit y1 x1 if y2==1
(output omitted)
. predict phat
(option pr assumed; Pr(y1))
```

Using the (marginal) predicted probabilities from the probit model with sample selection (`pmarg`) and the predicted probabilities from the (usual) probit model (`phat`), we can also generate the “true” predicted probabilities from the synthesized `y1s` variable and then compare the predicted probabilities:

```
. generate ptrue = normal(y1s)
. summarize pmarg ptrue phat
```

| Variable           | Obs   | Mean     | Std. dev. | Min      | Max     |
|--------------------|-------|----------|-----------|----------|---------|
| <code>pmarg</code> | 5,000 | .6089004 | .3249993  | .0632337 | .99354  |
| <code>ptrue</code> | 5,000 | .5967872 | .3534232  | 2.78e-07 | 1       |
| <code>phat</code>  | 5,000 | .6588519 | .3113716  | .0910951 | .997021 |

Here we see that ignoring the selection mechanism (comparing the `phat` variable with the true `ptrue` variable) results in predicted probabilities that are much higher than the true values. Looking at the marginal predicted probabilities from the model with sample selection, however, results in more accurate predictions.

[U] [20 Estimation and postestimation commands](#)

## Description

The `help` command displays help information about the specified command or topic. `help` launches a new Viewer to display help for the specified command or topic or displays help on the console in Stata for Unix(console). If `help` is not followed by a command or a topic name, Stata displays advice for using the help system and documentation.

## Menu

Help > Stata command...

## Syntax

```
help [command_or_topic_name] [, nonew name(viewername) marker(markername)]
```

## Options

`nonew` specifies that a new Viewer window not be opened for the help topic if a Viewer window is already open. The default is for a new Viewer window to be opened each time `help` is typed so that multiple help files may be viewed at once. `nonew` causes the help file to be displayed in the topmost open Viewer.

`name(viewername)` specifies that help be displayed in a Viewer window named *viewername*. If the named window already exists, its contents will be replaced. If the named window does not exist, it will be created.

`marker(markername)` specifies that the help file be opened to the position of *markername* within the help file.

## Remarks and examples

To obtain help for any Stata command, type `help command` or select **Help > Stata command...** and fill in *command*.

help is best explained by examples.

| To obtain help for ...           | type                                                |
|----------------------------------|-----------------------------------------------------|
| regress                          | help regress                                        |
| postestimation tools for regress | help regress postestimation or<br>help regress post |
| graph option xlabel()            | help graph xlabel()                                 |
| Stata function strpos()          | help strpos()                                       |
| Mata function optimize()         | help mata optimize()                                |

Tips:

- help displays advice for using the help system and documentation.
- help guide displays a table of contents for basic Stata concepts.
- help estimation commands displays an alphabetical listing of all Stata estimation commands.
- help functions displays help on Stata functions by category.
- help mata functions displays a subject table of contents for Mata's functions.
- help ts glossary displays the glossary for the time-series manual, and similarly for the other Stata specialty manuals.

If you type help *topic* and help for *topic* is not found, Stata will automatically perform a search for *topic*.

For instance, try typing help forecasting. A forecasting help file is not found, so Stata executes search forecasting and displays the results in the Viewer.

See [U] 4 Stata's help and search facilities for a complete description of how to use help.

## □ Technical note

When you type help *topic*, Stata first looks along the adopath for *topic*.sthlp; see [U] 17.5 Where does Stata look for ado-files?

## Description

`hetoprobit` fits a heteroskedastic ordered probit model for an ordinal dependent variable. `hetoprobit` is a generalization of `oprobit` that allows the variance to be modeled as a function of independent variables and to differ between subjects or groups in the population.

## Quick start

Heteroskedastic ordinal probit model of  $y$  on  $x1$ , using  $x2$  to model the variance

```
hetoprobit y x1, het(x2)
```

With robust standard errors

```
hetoprobit y x1, het(x2) vce(robust)
```

Perform a Wald test on the variance instead of a likelihood-ratio (LR) test

```
hetoprobit y x1, het(x2) waldhet
```

## Menu

Statistics > Ordinal outcomes > Heteroskedastic ordered probit regression

## Syntax

```
hetoprobit depvar [indepvars] [if] [in] [weight],
 het(varlist[, offset(varnameo)] [options])
```

\*het() is required. The full specification is het(*varlist* [, offset(*varname*<sub>o</sub>)]).

*indepvars* and *varlist* may contain factor variables; see [U] 11.4.3 **Factor variables**.

*depvar*, *indepvars*, and *varlist* may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

bayes, bayesboot, bootstrap, by, collect, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: hetoprobit**.

Weights are not allowed with the bootstrap prefix; see [R] **bootstrap**.

vce() and weights are not allowed with the svy prefix; see [SVY] **svy**.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 **weight**.

noheader, notable, collinear, and coeflegend do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options

### Model

`het(varlist [ , offset(varnameo) ])` specifies the independent variables and, optionally, the offset variable in the variance function. `het()` is required.

`offset(varnameo)` specifies that offset *varname<sub>o</sub>* be included in the variance model with the coefficient constrained to be 1.

`offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`waldhet` specifies that a Wald test of whether  $\ln\sigma = 0$  be performed instead of the LR test.

`nocnsreport`; see [R] [Estimation options](#).

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and  `nolstretch`; see [R] [Estimation options](#).

### Maximization

*maximize\_options*: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

The following options are available with `hetoprobit` but are not shown in the dialog box:

`noheader` suppresses the header above the coefficient table.

`notable` suppresses the display of the coefficient table.

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

`hetoprobit` fits a maximum-likelihood heteroskedastic ordered probit model, which is a generalization of the ordered probit model (see [R] [oprobit](#)).

In ordinal regression models, the outcome is an ordinal variable—a variable that is categorical and ordered, for instance, “poor”, “good”, and “excellent”. The specific values of the ordinal variable are irrelevant. It matters only that larger values are assumed to correspond to “higher” outcomes. To simplify the discussion in this entry, we assume without loss of generality that the dependent variable takes on the integer values  $0, 1, \dots, H$ , for some value  $H > 1$ .

In ordered probit models, an underlying score is estimated as a linear function of the independent variables and a set of cutpoints. The probability of observing outcome  $y_j = h$ , where  $h = 0, 1, \dots, H$ , corresponds to the probability that the value of the linear function, plus random error, is within the range of the cutpoints associated with the outcome

$$\begin{aligned} \Pr(y_j = h) &= \Pr(\kappa_h < \beta_1 x_{1j} + \beta_2 x_{2j} + \dots + \beta_k x_{kj} + u_j \leq \kappa_{h+1}) \\ &= \Phi(\kappa_{h+1} - \mathbf{x}_j \boldsymbol{\beta}) - \Phi(\kappa_h - \mathbf{x}_j \boldsymbol{\beta}) \end{aligned}$$

where  $\mathbf{x}_j = (x_{1j}, x_{2j}, \dots, x_{kj})$  are the  $k$  independent variables that model the mean function;  $\boldsymbol{\beta}$  is a column vector of unknown parameters in the mean function;  $u_j$ , where  $j = 1, \dots, N$ , are normally distributed error terms;  $\kappa_h$ , where  $h = 1, \dots, H$ , are the unknown cutpoints that separate the different possible values of  $h$ ; and  $\Phi(\cdot)$  is the cumulative distribution function of the standard normal distribution. Also, by convention, to complete the intervals for the lowest and highest values of the outcome,  $\kappa_0 = -\infty$  and  $\kappa_{H+1} = \infty$ .

In conventional ordinal probit models, the error term is assumed i.i.d. normal with unit variance for all observations. `hetoprobit` generalizes the ordered probit model by representing the variance of the error term  $u_j$  as a multiplicative function of explanatory variables  $\mathbf{z}_j = (z_{1j}, z_{2j}, \dots, z_{mj})$ . This approach was introduced by [Harvey \(1976\)](#), though we depart from Harvey slightly by modeling standard deviation rather than variance. More specifically, we model the natural logarithm of the standard deviation as a linear combination of the explanatory variables,

$$\ln \sigma_j = \mathbf{z}_j \boldsymbol{\gamma}$$

where  $\boldsymbol{\gamma}$  is a column vector of unknown parameters in the variance function.

With this generalization, the error variance may differ between subjects or between groups in the population, and

$$\Pr(y_j = h) = \Phi \left\{ \frac{\kappa_{h+1} - \mathbf{x}_j \boldsymbol{\beta}}{\exp(\mathbf{z}_j \boldsymbol{\gamma})} \right\} - \Phi \left\{ \frac{\kappa_h - \mathbf{x}_j \boldsymbol{\beta}}{\exp(\mathbf{z}_j \boldsymbol{\gamma})} \right\}$$

For the model to be identifiable, there can be no constant term in  $\mathbf{z}_j \boldsymbol{\gamma}$ . Also, as with [\[R\] oprobit](#), there is no constant term in  $\mathbf{x}_j \boldsymbol{\beta}$ . The role of the constant is subsumed by the cutpoints.

We estimate the coefficients  $\beta_1, \beta_2, \dots, \beta_k$  and  $\gamma_1, \gamma_2, \dots, \gamma_m$  together with the cutpoints  $\kappa_1, \kappa_2, \dots, \kappa_H$ . If the model has no independent variables in  $\mathbf{x}_j$ , only the cutpoints and the  $\boldsymbol{\gamma}$  parameters are estimated.

Modeling of heteroskedastic variance has both constructive and defensive uses. It is known that differences in variance between subjects or between groups in the population can cause biased coefficient estimates and can complicate comparison of distinct groups. Thus, incorporating a model for variance can be necessary for proper inference, even if the variance function itself is not a topic of interest to the researcher. For discussion, see [Williams \(2010\)](#) and the references cited therein. There are also cases where modeling the differences between variances of different subjects or different groups in the population is one of the principal purposes of the study. We will discuss such a scenario in the examples below. See [Reardon et al. \(2017\)](#) and [Alvarez and Brehm \(1995\)](#) for additional examples.

### ▷ Example 1: Modeling heteroskedasticity of reported health status

In this example, we will use a slightly modified subset of data from the 2015 Eating & Health Module of the American Time Use Survey (ATUS), conducted by the US Bureau of Labor Statistics. Our analysis will not account for the survey design. The ATUS measures the amount of time people spend doing various activities, such as working, caring for children, volunteering, and socializing. Of interest to us is an ordinal response variable, `health`, which contains individuals' self-assessments of their overall health status on a five-point scale: 1 for "poor", 2 for "fair", 3 for "good", 4 for "very good", and 5 for "excellent".

We want to examine the role that age and other factors play in an individual's self-assessment of health. Age is a natural variable to include when modeling mean or typical health status. But we also suspect that the variation in health status is greater in an older population, as compared with a youthful population, which consists mainly of healthy individuals. If our suspicion is true, quantifying the relationship between variation in health status and age may have value, for example, in planning a healthcare strategy that is appropriately tailored both for the older Medicare population and for a younger cohort.

Thus, we will use `hetoprobit` to model heteroskedasticity induced by age. In modeling the variance term, in addition to age, we will include a factor variable, `exercise`, which indicates whether or not an individual exercised during the previous week. For purposes of illustration, imagine that we are not interested in exercise as a topic in its own right, but we are concerned that health variability among those who exercise may differ from the variability among those who do not. Therefore, we include `exercise` in the variance term to help insulate our estimation results against a possible hidden bias.

Our model will include three explanatory variables for the mean function: `age`, `bmi` (body mass index), and `exercise`.

| /cut4    | -.4189882   | .1524084  |       |       | -.7177031            | -.1202733 |

```
LR test of lnsigma=0: chi2(2) = 16.84
Prob > chi2 = 0.0002
```

The LR test at the bottom of the output is a test of homogeneity of the variance function. The  $\chi^2(2)$  statistic of 16.84 is significant, indicating that heteroskedasticity is present. If you prefer the Wald test for heteroskedasticity, you can specify the `waldhet` option. The coefficients for the variance function are reported in the section of the table labeled `lnsigma`. Our results indicate that `age` is a significant contributor to the variance function but that `exercise` is not significant at a 0.05 level.

The LR test for the model that appears above the coefficient table is a joint test for inclusion of `age`, `bmi`, and `exercise` in the mean function. The null model for this test is the model consisting only of cutpoints and the heteroskedastic term. Coefficients for the mean function are reported in the section of the table labeled `health`. In this example, `age`, `bmi`, and `exercise` are significant components of the linear predictor of the mean.

The signs of the coefficients in the fitted model are directly interpretable. For example, the negative value for the coefficient of `bmi` implies that higher values of `bmi` predict lower values of health status. However, because of the probit link and the fact that we estimate variance with a log transformation, the numerical relationships between the coefficients of the model and the outcome variables are nonlinear. Postestimation commands recognize and account for these nonlinearities.

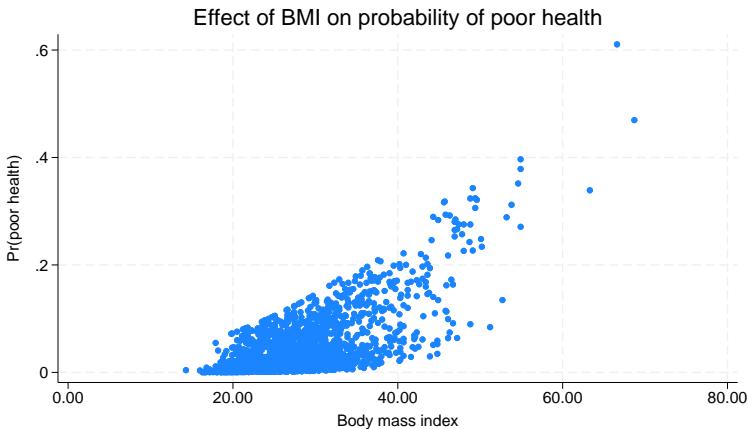

### ▷ Example 2: Predict the probability of a poor health rating

Ordered probit models allow us to look at the probabilities of different outcomes of interest. Suppose we are interested in predictions of a reported health status of "poor" (`health = 1`) and how it differs across levels of `bmi`. First, we obtain the predicted probability of poor health.

```
. predict pr1, pr outcome(1)
```

We can now visualize how the predicted probability of poor health status differs across the range of `bmi` values in our sample.

```
. twoway scatter pr1 bmi, ytitle("Pr(poor health)")
> title("Effect of BMI on probability of poor health")
```

We see that predicted probabilities of poor health increase as body mass index increases.

### ▷ Example 3: Predictive margins and average marginal effect

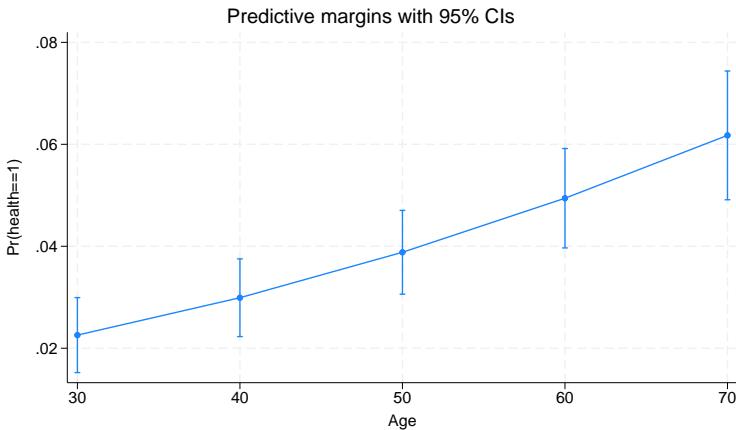

The graph [above](#) plots the predicted probability of poor health for each individual in our dataset. We may also want to evaluate how the average predicted probability changes across levels of the covariates in the model. For instance, we can use the `margins` command to obtain the expected probability of having poor health across a range of ages.

```
. margins, at(age = (30(10)70)) predict(outcome(1))
Predictive margins Number of obs = 2,009
Model VCE: OIM
Expression: Pr(health==1), predict(outcome(1))
1._at: age = 30
2._at: age = 40
3._at: age = 50
4._at: age = 60
5._at: age = 70
```

|     | Margin   | Delta-method<br>std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|----------|---------------------------|------|-------|----------------------|----------|
| _at |          |                           |      |       |                      |          |
| 1   | .0225765 | .0037522                  | 6.02 | 0.000 | .0152224             | .0299306 |
| 2   | .0299079 | .0038887                  | 7.69 | 0.000 | .0222862             | .0375297 |
| 3   | .0388244 | .0041936                  | 9.26 | 0.000 | .0306051             | .0470438 |
| 4   | .0494246 | .0049748                  | 9.93 | 0.000 | .0396742             | .0591751 |
| 5   | .0617532 | .0064443                  | 9.58 | 0.000 | .0491226             | .0743839 |

Based on our model, what would we expect if everyone was 30 years old but had the same distributions of bmi and exercise that we observed in our data? The first line in this table reports that the average predicted probability of poor health is 0.0226 in this case. The second line shows the average predicted probability of poor health if we set age = 40, and so on. We find that for age = 70, the average probability of reporting a poor health status has increased to 0.0618. We can visualize this by typing marginsplot after margins.

```
. marginsplot
Variables that uniquely identify margins: age
```

We have focused on the prediction of poor health. We could instead simultaneously obtain average predicted probabilities of poor, fair, good, very good, and excellent health status and plot them across our requested age range. In that case, we would type

```
. margins, at(age = (30(10)70))
. marginsplot
```

We might also be interested in characterizing the relationship between bmi and the probability of reporting poor health. The coefficients and cutpoints reported in `hetoprobit` are not easily interpreted. We can, however, use `margins` to estimate the average marginal effect of `bmi` on the probability of reporting poor health. Because the average marginal effect depends on the value of `bmi`, we estimate it across a range of `bmi` values by typing

```
. margins, dydx(bmi) at(bmi = (20(5)35)) predict(outcome(1))
Average marginal effects Number of obs = 2,009
Model VCE: OIM
Expression: Pr(health==1), predict(outcome(1))
dy/dx wrt: bmi
1._at: bmi = 20
2._at: bmi = 25
3._at: bmi = 30
4._at: bmi = 35
```

|     |     | Delta-method |           | z    | P> z  | [95% conf. interval] |          |
|-----|-----|--------------|-----------|------|-------|----------------------|----------|
|     |     | dy/dx        | std. err. |      |       |                      |          |
| bmi |     |              |           |      |       |                      |          |
|     | _at |              |           |      |       |                      |          |
|     | 1   | .0015875     | .0001721  | 9.23 | 0.000 | .0012503             | .0019248 |

|     | 3   | .0036447     | .0004377  | 8.33 | 0.000 | .0027868             | .0045027 |
|     | 4   | .0052124     | .0007013  | 7.43 | 0.000 | .0038379             | .006587  |

The average marginal effect of `bmi` on the probability of reporting poor health increases as `bmi` itself increases.

### ► Example 4: Interpreting the variance function

From the output of our `hetoprobit` command, we determined that variance of health status is affected by age. Let's consider to what extent. In this example, we assess the effect of age on the variance by using the `margins` command. We use the `predict(sigma)` option to obtain the average predicted standard deviation of the errors. We will look at ages 15 and 85, which are the youngest and oldest ages, respectively, in our dataset.

```
. margins, predict(sigma) at(age = (15,85)) noatlegend
Predictive margins Number of obs = 2,009
Model VCE: OIM
Expression: Heteroskedastic standard deviation, predict(sigma)
```

|  |     | Delta-method |           | z     | P> z  | [95% conf. interval] |          |
|--|-----|--------------|-----------|-------|-------|----------------------|----------|
|  |     | Margin       | std. err. |       |       |                      |          |
|  | _at |              |           |       |       |                      |          |
|  | 1   | 1.014732     | .0320905  | 31.62 | 0.000 | .9518354             | 1.077628 |
|  | 2   | 1.355853     | .1398144  | 9.70  | 0.000 | 1.081822             | 1.629884 |

Variation increases with age. The expected standard deviation of the error term changes from 1.015 at age 15 to 1.356 at age 85.

## Stored results

hetoprobit stores the following in `e()`:

### Scalars

|                            |                                                       |

|                 |                                              |
|-----------------|----------------------------------------------|
| Matrices        |                                              |
| e(b)            | coefficient vector                           |
| e(Cns)          | constraints matrix                           |
| e(iolog)        | iteration log (up to 20 iterations)          |
| e(gradient)     | gradient vector                              |
| e(cat)          | category values                              |
| e(V)            | variance–covariance matrix of the estimators |
| e(V_modelbased) | model-based variance                         |
| Functions       |                                              |
| e(sample)       | marks estimation sample                      |

In addition to the above, the following is stored in `r()`:

|          |                                                                                                                            |
|----------|----------------------------------------------------------------------------------------------------------------------------|
| Matrices |                                                                                                                            |
| r(table) | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

`hetoprobit` fits a cumulative probit model with heteroskedastic variance using maximum likelihood estimation. Namely, the model is that, for a subject with explanatory variables  $\mathbf{x}$  and  $\mathbf{z}$ ,

$$\Pr(Y \leq h) = \Phi \left\{ \frac{\kappa_{h+1} - \mathbf{x}\boldsymbol{\beta}}{\exp(\mathbf{z}\boldsymbol{\gamma})} \right\}$$

where  $Y$  is an ordinal outcome taking on values  $h = 0, 1, \dots, H$ , and  $\Phi(\cdot)$  is the cdf of the standard normal distribution. The value  $\kappa_{h+1}$  is a cutpoint that separates the region corresponding to  $Y = h$  from regions for higher-valued categories. The effects  $\boldsymbol{\beta}$  and the effects  $\boldsymbol{\gamma}$  are the same for each cumulative probability.

The log-likelihood function is

$$\ln L = \sum_{j=1}^N w_j \sum_{h=0}^H I_h(y_j) \ln \left[ \Phi \left\{ \frac{\kappa_{h+1} - \mathbf{x}_j \boldsymbol{\beta}}{\exp(\mathbf{z}_j \boldsymbol{\gamma})} \right\} - \Phi \left\{ \frac{\kappa_h - \mathbf{x}_j \boldsymbol{\beta}}{\exp(\mathbf{z}_j \boldsymbol{\gamma})} \right\} \right]$$

where

$$I_h(y_j) = \begin{cases} 1 & \text{if } y_j = h \\ 0 & \text{otherwise} \end{cases}$$

and  $y_j$ , where  $j = 1, \dots, N$ , is an observed value of  $Y$ ;  $w_j$  are optional weights;  $\kappa_0 = -\infty$  and  $\kappa_{H+1} = \infty$ ; and all other terminology is defined in [Remarks and examples](#) above.

The log-likelihood function is maximized as described in [\[R\] Maximize](#).

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [\[P\] \\_robust](#), particularly [Maximum likelihood estimators](#) and [Methods and formulas](#).

`hetoprobit` also supports estimation with survey data. For details on VCEs with survey data, see [\[SVY\] Variance estimation](#).

## Postestimation commands

The following postestimation commands are available after `hetoprobit`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |

\*`forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.

## predict

### Description for predict

`predict` creates a new variable containing predictions such as probabilities, linear predictions, and standard deviations.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

```
predict [type] { stub* | newvar | newvarlist } [if] [in] [, statistic
outcome(outcome) nooffset]
```

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                    |                                         |
|--------------------|-----------------------------------------|
| <code>pr</code>    | predicted probabilities; the default    |
| <code>xb</code>    | linear prediction                       |
| <code>stdp</code>  | standard error of the linear prediction |
| <code>sigma</code> | standard deviation of the error term    |

You specify one or  $k$  new variables with `pr`, where  $k$  is the number of outcomes. If you specify one new variable and you do not specify `outcome()`, then `outcome(#1)` is assumed.

You specify one new variable with `xb`, `stdp`, or `sigma`.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

### Options for predict

Main

`pr`, the default, computes the predicted probabilities for all outcomes or for a specific outcome. To compute probabilities for all outcomes, you specify  $k$  new variables, where  $k$  is the number of categories of the dependent variable. Alternatively, you can specify `stub*`; in which case, `pr` will store predicted probabilities in variables `stub1`, `stub2`, ..., `stubk`. To compute the probability for a specific outcome, you specify one new variable and, optionally, the outcome value in option `outcome()`; if you omit `outcome()`, the first outcome value, `outcome(#1)`, is assumed.

Say that you fit a model by typing `estimation_cmd y x1 x2`, and `y` takes on four values. Then, you could type `predict p1 p2 p3 p4` to obtain all four predicted probabilities; alternatively, you could type `predict p*` to generate the four predicted probabilities. To compute specific probabilities one at a time, you can type `predict p1, outcome(#1)` (or simply `predict p1`), `predict p2, outcome(#2)`, and so on. See option `outcome()` for other ways to refer to outcome values.

`xb` calculates the linear prediction. The linear prediction is defined by ignoring the contribution of the estimated cutpoints.

`stdp` calculates the standard error of the linear prediction.

`sigma` calculates the standard deviation of the error term.

`outcome(outcome)` specifies for which outcome the predicted probabilities are to be calculated. `outcome()` should contain either one value of the dependent variable or one of #1, #2, ..., with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc. `outcome()` is available only with the default `pr` option.

`nooffset` is relevant only if you specified `offset(varname)` for `hetoprobit` or within the `het()` option. `nooffset` modifies the calculations made by `predict` so that they ignore the offset variable: the linear prediction is treated as  $\mathbf{x}_j\mathbf{b}$  rather than as  $\mathbf{x}_j\mathbf{b} + \text{offset}_j^b$ , and the prediction of  $\ln(\sigma)$  is treated as  $\mathbf{z}_j\mathbf{g}$  rather than as  $\mathbf{z}_j\mathbf{g} + \text{offset}_j^g$ . `nooffset` is not allowed with `scores`.

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\mathbf{b})$ .

The next new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$ .

The next new variable will contain  $\partial \ln L / \partial \kappa_1$ .

The next new variable (if any) will contain  $\partial \ln L / \partial \kappa_2$ .

...

The last new variable will contain  $\partial \ln L / \partial \kappa_H$ , where  $\kappa_h$  for  $h = 1, 2, \dots, H$  refers to the  $h$ th cutpoint. If the linear predictor had no `indepvars`, the first new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$ .

# margins

## Description for margins

`margins` estimates margins of response for probabilities, linear predictions, and standard deviations.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i> | Description                           |
|------------------|---------------------------------------|
| Main             |                                       |
| default          | probabilities for each outcome        |
| pr               | probability for a specified outcome   |
| xb               | linear prediction                     |
| stdp             | not allowed with <code>margins</code> |
| sigma            | standard deviation of the error term  |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## Remarks and examples

See [U] [20 Estimation and postestimation commands](#) for an overview of postestimation commands, including information on obtaining the variance–covariance matrix of the estimators, predicted values, and hypothesis tests.

Once you have fit a model with `hetoprobit`, you may use the `predict` command to obtain the predicted probabilities for both the estimation sample and other samples. With the `pr` option, `predict` calculates the predicted probability of one or all ordinal value outcomes. With the `xb` option, `predict` calculates the linear prediction,  $\mathbf{x}_j\mathbf{b}$ , where  $\mathbf{x}_j$  are the independent variables in the  $j$ th observation and  $\mathbf{b}$  is the estimated parameter vector. The linear prediction is defined ignoring the contribution of the cutpoints. With the `sigma` option, `predict` calculates the predicted standard deviations of the error term,  $\sigma_j = \exp(\mathbf{z}_j\mathbf{g})$ , where  $\mathbf{g}$  is the estimated coefficient vector for the variance model.

See [example 2](#) in [R] [hetoprobit](#) for an example of `predict` after `hetoprobit`. In [example 3](#) and [example 4](#), we demonstrate how to use `margins` to obtain marginal effects, to compute expected probabilities of outcome levels across values of covariates, and to characterize the variance as a function of covariates.

## Methods and formulas

For definitions of the terminology used in this section, see *Remarks and examples* in [R] [hetoprobit](#).

For outcome  $h$ , the statistic `pr` is the estimated predicted probability

$$\widehat{\text{Pr}}(y_j = h) = \Phi \left\{ \frac{\widehat{\kappa}_{h+1} - \mathbf{x}_j \mathbf{b}}{\exp(\mathbf{z}_j \mathbf{g})} \right\} - \Phi \left\{ \frac{\widehat{\kappa}_h - \mathbf{x}_j \mathbf{b}}{\exp(\mathbf{z}_j \mathbf{g})} \right\}$$

where  $\mathbf{x}_j \mathbf{b}$  and  $\mathbf{z}_j \mathbf{g}$  are the linear predictions of the regression and variance models, respectively, for the  $j$ th subject.

The statistic `sigma` is the estimated standard deviation of the modeled heteroskedastic error, namely,

$$\widehat{\sigma}_j = \exp(\mathbf{z}_j \mathbf{g})$$

If you specified `offset(varname)` with `hetoprobit` or within the `het()` option (and if you do not specify option `nooffset` with `predict`), then the specified offsets are applied by `predict`. Namely, the linear prediction is computed as  $\mathbf{x}_j \mathbf{b} + \text{offset}_j^b$ ; the prediction of  $\ln(\sigma)$  is computed as  $\mathbf{z}_j \mathbf{g} + \text{offset}_j^g$ ; and all other statistics are based on the resulting predictions. If you specify `nooffset` with `predict`, then the linear prediction is  $\mathbf{x}_j \mathbf{b}$  and the prediction of  $\ln(\sigma)$  is  $\mathbf{z}_j \mathbf{g}$ , regardless of whether you specified the `offset()` option with `hetoprobit` or within `het()`.

## Description

`hetprobit` fits a maximum-likelihood heteroskedastic probit model.

## Quick start

Heteroskedastic probit model of  $y$  on  $x1$ , using  $x2$  to model the variance

```
hetprobit y x1, het(x2)
```

With robust standard errors

```
hetprobit y x1, het(x2) vce(robust)
```

After fitting a model, reprint the table as a coefficient legend

```
hetprobit, coeflegend
```

## Menu

Statistics > Binary outcomes > Heteroskedastic probit regression

## Syntax

```
hetprobit depvar [indepvars] [if] [in] [weight] ,
 het(varlist [, offset(varnameo)]) [options]
```

| <i>coeflegend</i>                         | display legend instead of statistics                                                                                                             |

\**het*() is required. The full specification is *het*(*varlist* [ , *offset*(*varname*<sub>o</sub>) ]).

*indepvars* and *varlist* may contain factor variables; see [U] 11.4.3 **Factor variables**.

*depvar*, *indepvars*, and *varlist* may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

*bayes*, *bayesboot*, *bootstrap*, *by*, *collect*, *fp*, *jackknife*, *rolling*, *statsby*, and *svy* are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: hetprobit**.

Weights are not allowed with the *bootstrap* prefix; see [R] **bootstrap**.

*vce*() , *lrmodel*, and weights are not allowed with the *svy* prefix; see [SVY] **svy**.

*fweights*, *iweights*, and *pweights* are allowed; see [U] 11.1.6 **weight**.

*collinear* and *coeflegend* do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options

### Model

`het` (*varlist* [ , `offset` (*varname<sub>o</sub>*) ]) specifies the independent variables and, optionally, the offset variable in the variance function. `het()` is required.

`offset` (*varname<sub>o</sub>*) specifies that selection offset *varname<sub>o</sub>* be included in the model with the coefficient constrained to be 1.

`noconstant`, `offset` (*varname*); see [R] [Estimation options](#).

`asis` forces the retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] [probit](#).

`constraints` (*constraints*); see [R] [Estimation options](#).

### SE/Robust

`vce` (*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level` (*#*), `lrmmodel`; see [R] [Estimation options](#).

`waldhet` specifies that a Wald test of whether  $\ln\sigma = 0$  be performed instead of the LR test.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `novlabel`, `fvwrap` (*#*), `fvwrapon` (*style*), `cformat` (*%fmt*), `pformat` (*%fmt*), `sformat` (*%fmt*), and `no1stretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique` (*algorithm\_spec*), `iterate` (*#*), `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance` (*#*), `ltolerance` (*#*), `nrtolerance` (*#*), `nonrtolerance`, and `from` (*init\_specs*); see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique` (`bhhh`) resets the default *vcetype* to `vce` (`opg`).

The following options are available with `hetprobit` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

*Introduction*

*Robust standard errors*

### Introduction

`hetprobit` fits a maximum-likelihood heteroskedastic probit model, which is a generalization of the probit model. Let  $y_j, j = 1, \dots, N$ , be a binary outcome variable taking on the value 0 (failure) or 1 (success). In the probit model, the probability that  $y_j$  takes on the value 1 is modeled as a nonlinear function of a linear combination of the  $k$  independent variables  $\mathbf{x}_j = (x_{1j}, x_{2j}, \dots, x_{kj})$ ,

$$\Pr(y_j = 1) = \Phi(\mathbf{x}_j\mathbf{b})$$

in which  $\Phi(\cdot)$  is the cumulative distribution function (CDF) of a standard normal random variable, that is, a normally distributed (Gaussian) random variable with mean 0 and variance 1. The linear combination of the independent variables,  $\mathbf{x}_j\mathbf{b}$ , is commonly called the *index function*, or *index*. Heteroskedastic probit generalizes the probit model by generalizing  $\Phi(\cdot)$  to a normal CDF with a variance that is no longer fixed at 1 but can vary as a function of the independent variables. `hetprobit` models the variance as a multiplicative function of these  $m$  variables  $\mathbf{z}_j = (z_{1j}, z_{2j}, \dots, z_{mj})$ , following [Harvey \(1976\)](#):

$$\sigma_j^2 = \{ \exp(\mathbf{z}_j\boldsymbol{\gamma}) \}^2$$

Thus, the probability of success as a function of all the independent variables is

$$\Pr(y_j = 1) = \Phi\left\{ \mathbf{x}_j\mathbf{b} / \exp(\mathbf{z}_j\boldsymbol{\gamma}) \right\}$$

From this expression, it is clear that, unlike the index  $\mathbf{x}_j\mathbf{b}$ , no constant term can be present in  $\mathbf{z}_j\boldsymbol{\gamma}$  if the model is to be identifiable.

Suppose that the binary outcomes  $y_j$  are generated by thresholding an unobserved random variable,  $w$ , which is normally distributed with mean  $\mathbf{x}_j\mathbf{b}$  and variance 1 such that

$$y_j = \begin{cases} 1 & \text{if } w_j > 0 \\ 0 & \text{if } w_j \leq 0 \end{cases}$$

This process gives the probit model:

$$\Pr(y_j = 1) = \Pr(w_j > 0) = \Phi(\mathbf{x}_j\mathbf{b})$$

Now, suppose that the unobserved  $w_j$  are heteroskedastic with variance

$$\sigma_j^2 = \{ \exp(\mathbf{z}_j\boldsymbol{\gamma}) \}^2$$

Relaxing the homoskedastic assumption of the probit model in this manner yields our multiplicative heteroskedastic probit model:

$$\Pr(y_j = 1) = \Phi\left\{ \mathbf{x}_j\mathbf{b} / \exp(\mathbf{z}_j\boldsymbol{\gamma}) \right\}$$

► Example 1

For this example, we generate simulated data for a simple heteroskedastic probit model and then estimate the coefficients with `hetprobit`:

```
. set obs 1000
Number of observations (_N) was 0, now 1,000.
. set seed 1234567
. generate x = 1-2*runiform()
. generate xhet = runiform()
. generate sigma = exp(1.5*xhet)
. generate p = normal((0.3+2*x)/sigma)
. generate y = cond(runiform()<=p,1,0)
. hetprobit y x, het(xhet)
```

Fitting probit model:

```
Iteration 0: Log likelihood = -688.33746
Iteration 1: Log likelihood = -610.48362
Iteration 2: Log likelihood = -610.3626
Iteration 3: Log likelihood = -610.3626
```

Fitting full model:

```
Iteration 0: Log likelihood = -610.3626
Iteration 1: Log likelihood = -600.8767
Iteration 2: Log likelihood = -600.10154
Iteration 3: Log likelihood = -600.01544
Iteration 4: Log likelihood = -600.01521
Iteration 5: Log likelihood = -600.01521
```

Heteroskedastic probit model

```
Number of obs = 1,000
Zero outcomes = 451
Nonzero outcomes = 549
Wald chi2(1) = 54.20
Prob > chi2 = 0.0000
```

Log likelihood = -600.0152

|         | y     | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|---------|-------|-------------|-----------|------|-------|----------------------|----------|
| y       | x     | 1.782479    | .2421117  | 7.36 | 0.000 | 1.307949             | 2.257009 |
|         | _cons | .3140616    | .0871121  | 3.61 | 0.000 | .1433249             | .4847982 |
| lnsigma | xhet  | 1.31152     | .3011689  | 4.35 | 0.000 | .7212402             | 1.901801 |

LR test of lnsigma=0: chi2(1) = 20.69

Prob > chi2 = 0.0000

Above, we created two variables, `x` and `xhet`, and then simulated the model

$$\Pr(y = 1) = F\left\{(\beta_0 + \beta_1 x) / \exp(\gamma_1 xhet)\right\}$$

for  $\beta_0 = 0.3$ ,  $\beta_1 = 2$ , and  $\gamma_1 = 1.5$ . According to `hetprobit`'s output, all coefficients are significant, and, as we would expect, the Wald test of the full model versus the constant-only model—for example, the index consisting of  $\beta_0 + \beta_1 x$  versus that of just  $\beta_0$ —is significant with  $\chi^2(1) = 54$ . Likewise, the likelihood-ratio test of heteroskedasticity, which tests the full model with heteroskedasticity against the full model without, is significant with  $\chi^2(1) = 21$ . See [R] [Maximize](#) for more explanation of the output. For this simple model, `hetprobit` took five iterations to converge. As stated elsewhere ([Greene 2018, 764](#)), this is a difficult model to fit, and it is not uncommon for it to require many iterations or for the optimizer to print out warnings and informative messages during the optimization. Slow convergence is especially common for models in which one or more of the independent variables appear in both the index and variance functions.

□ Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

### Robust standard errors

If you specify the `vce(robust)` option, `hetprobit` reports robust standard errors as described in [\[U\] 20.22 Obtaining robust variance estimates](#). To illustrate the effect of this option, we will reestimate our coefficients by using the same model and data in our example, this time adding `vce(robust)` to our `hetprobit` command.

▷ Example 2

```
. hetprobit y x, het(xhet) vce(robust) nolog
Heteroskedastic probit model Number of obs = 1,000
 Zero outcomes = 451
 Nonzero outcomes = 549
 Wald chi2(1) = 50.49
 Prob > chi2 = 0.0000
Log pseudolikelihood = -600.0152
```

| y       | Robust      |           | z    | P> z  | [95% conf. interval] |          |
|---------|-------------|-----------|------|-------|----------------------|----------|
|         | Coefficient | std. err. |      |       |                      |          |
| x       | 1.782479    | .2508447  | 7.11 | 0.000 | 1.290832             | 2.274126 |
| _cons   | .3140616    | .087195   | 3.60 | 0.000 | .1431625             | .4849607 |
| lnsigma |             |           |      |       |                      |          |
| xhet    | 1.31152     | .3059137  | 4.29 | 0.000 | .7119406             | 1.9111   |

```
Wald test of lnsigma=0: chi2(1) = 18.38 Prob > chi2 = 0.0000
```

The `vce(robust)` standard errors for two of the three parameters are larger than the previously reported conventional standard errors. This is to be expected, even though (by construction) we have perfect model specification because this option trades off efficient estimation of the coefficient variance–covariance matrix for robustness against misspecification.

Specifying the `vce(cluster clustvar)` option relaxes the usual assumption of independence between observations to the weaker assumption of independence just between clusters; that is, `hetprobit`, `vce(cluster clustvar)` is robust with respect to within-cluster correlation. This option is less efficient than the `xtgee` population-averaged models because `hetprobit` inefficiently sums within cluster for the standard error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation.

## Stored results

`hetprobit` stores the following in `e()`:

### Scalars

|                            |                                                   |

| e(ilog)         | iteration log (up to 20 iterations)          |
| e(gradient)     | gradient vector                              |
| e(V)            | variance–covariance matrix of the estimators |
| e(V_modelbased) | model-based variance                         |

## Functions

|           |                         |
|-----------|-------------------------|
| e(sample) | marks estimation sample |
|-----------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|          |                                                                                                                            |
|----------|----------------------------------------------------------------------------------------------------------------------------|
| r(table) | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |
|----------|----------------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

The heteroskedastic probit model is a generalization of the probit model because it allows the scale of the inverse link function to vary from observation to observation as a function of the independent variables.

The log-likelihood function for the heteroskedastic probit model is

$$\ln L = \sum_{j \in S} w_j \ln \Phi\{\mathbf{x}_j \boldsymbol{\beta} / \exp(\mathbf{z}_j \boldsymbol{\gamma})\} + \sum_{j \notin S} w_j \ln [1 - \Phi\{\mathbf{x}_j \boldsymbol{\beta} / \exp(\mathbf{z}_j \boldsymbol{\gamma})\}]$$

where  $S$  is the set of all observations  $j$  such that  $y_j \neq 0$  and  $w_j$  denotes the optional weights.  $\ln L$  is maximized as described in [R] [Maximize](#).

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] [\\_robust](#), particularly *Maximum likelihood estimators* and *Methods and formulas*.

`hetprobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

## Postestimation commands

The following postestimation commands are available after `hetprobit`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | probabilities, linear predictions, etc.                                                                                                 |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as probabilities, linear predictions, and standard deviations.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                    |                                                |
|--------------------|------------------------------------------------|
| <code>pr</code>    | probability of a positive outcome; the default |
| <code>xb</code>    | linear prediction                              |
| <code>sigma</code> | standard deviation of the error term           |

These statistics are available both in and out of sample; type `predict . . . if e(sample) . . .` if wanted only for the estimation sample.

## Options for predict

Main

`pr`, the default, calculates the probability of a positive outcome.

`xb` calculates the linear prediction.

`sigma` calculates the standard deviation of the error term.

`nooffset` is relevant only if you specified `offset(varname)` for `hetprobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j\mathbf{b}$  rather than as  $\mathbf{x}_j\mathbf{b} + \text{offset}_j$ .

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{z}_j\boldsymbol{\gamma})$ .

# margins

## Description for margins

`margins` estimates margins of response for probabilities, linear predictions, and standard deviations.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```

margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]

```

| <i>statistic</i>   | Description                                    |
|--------------------|------------------------------------------------|
| <code>pr</code>    | probability of a positive outcome; the default |
| <code>xb</code>    | linear prediction                              |
| <code>sigma</code> | standard deviation of the error term           |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## Remarks and examples

Once you have fit a model, you can use the `predict` command to obtain the predicted probabilities for both the estimation sample and other samples; see [U] [20 Estimation and postestimation commands](#) and [R] [predict](#). `predict` without arguments calculates the predicted probability of a positive outcome. With the `xb` option, `predict` calculates the index function combination,  $\mathbf{x}_j\mathbf{b}$ , where  $\mathbf{x}_j$  are the independent variables in the  $j$ th observation and  $\mathbf{b}$  is the estimated parameter vector. With the `sigma` option, `predict` calculates the predicted standard deviation,  $\sigma_j = \exp(\mathbf{z}_j\boldsymbol{\gamma})$ .

## ▷ Example 1

We use `predict` to compute the predicted probabilities and standard deviations based on the model in [example 2](#) in [\[R\] hetprobit](#) to compare these with the actual values:

```
. predict phat
(option pr assumed; Pr(y))
. generate diff_p = phat - p
. summarize diff_p
```

| Variable | Obs   | Mean     | Std. dev. | Min       | Max      |
|----------|-------|----------|-----------|-----------|----------|
| diff_p   | 1,000 | .0082805 | .0103027  | -.0169849 | .0396469 |

```
. predict sigmahat, sigma
. generate diff_s = sigmahat - sigma
. summarize diff_s
```

| Variable | Obs   | Mean      | Std. dev. | Min       | Max      |
|----------|-------|-----------|-----------|-----------|----------|
| diff_s   | 1,000 | -.2579493 | .2126614  | -.7661171 | -.000025 |

[Description](#)[Menu](#)[Options for maximum likelihood estimation](#)[Remarks and examples](#)[Methods and formulas](#)[Also see](#)[Quick start](#)[Syntax](#)[Options for two-step GLS estimation](#)[Stored results](#)[References](#)

## Description

`hetregress` fits a multiplicative heteroskedastic linear regression by modeling the variance as an exponential function of the specified variables using either maximum likelihood (ML; the default) or Harvey's two-step generalized least-squares (GLS) method.

## Quick start

Heteroskedastic regression model of  $y$  on  $x_1$ , using  $x_2$  to model the variance

```
hetregress y x1, het(x2)
```

Using Harvey's two-step GLS estimator instead of the default ML

```
hetregress y x1, het(x2) twostep
```

With robust standard errors

```
hetregress y x1, het(x2) vce(robust)
```

Perform a Wald test on the variance instead of a likelihood-ratio (LR) test

```
hetregress y x1, het(x2) waldhet
```

## Menu

Statistics > Linear models and related > Heteroskedastic linear regression

## Syntax

### Maximum likelihood estimation

```
hetregress depvar [indepvars] [if] [in] [weight] [, ml_options]
```

### Two-step GLS estimation

```
hetregress depvar [indepvars] [if] [in], twostep het(varlist) [ts_options]
```

### *ml\_options*

### Description

| <code>coeflegend</code>      | display legend instead of statistics                                                                                                             |

\*`twostep` and `het()` are required.

*indepvars* and *varlist* may contain factor variables; see [U] 11.4.3 **Factor variables**.

*depvar*, *indepvars*, and *varlist* may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: hetregress**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`aweight`s are not allowed with the `jackknife` prefix; see [R] **jackknife**.

`vce()`, `lrmmodel`, `twostep`, and `weights` are not allowed with the `svy` prefix; see [SVY] **svy**.

`aweight`s, `fweight`s, `weight`s, and `pweight`s are allowed with maximum likelihood estimation; see [U] 11.1.6 **weight**.

`collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options for maximum likelihood estimation

### Model

`mle` requests that the maximum likelihood estimator be used. This is the default.

`het (varlist)` specifies the independent variables in the variance function. When the `het()` option is not specified, homoskedasticity is assumed and the `waldhet` option is not allowed.

`noconstant`, `constraints(constraints)`; see [R] **Estimation options**.

### SE/Robust

`vce(vctype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] **vce\_option**.

## Reporting

`level(#)`, `lrmodel`; see [R] [Estimation options](#).

`waldhet` specifies that the Wald test of whether  $\ln\sigma^2 = 0$  be performed instead of the LR test.

`nocnsreport`; see [R] [Estimation options](#).

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

## Maximization

*maximize\_options*: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following options are available with `hetregress` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Options for two-step GLS estimation

## Model

`twostep` specifies that the model be fit using Harvey's two-step GLS estimator. This option requires that the independent variables be specified in the `het()` option to model the variance.

`het(varlist)` specifies the independent variables in the variance function.

`noconstant`; see [R] [Estimation options](#).

## SE

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`conventional`) and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

`vce(conventional)`, the default, uses the two-step variance estimator derived by Heckman.

## Reporting

`level(#)`; see [R] [Estimation options](#).

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

The following option is available with `hetregress` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

[Introduction](#)  
[Maximum likelihood estimation](#)  
[Two-step GLS estimation](#)

### Introduction

`hetregress` fits a multiplicative heteroskedastic linear regression model using either ML or Harvey's two-step GLS method. Multiplicative heteroskedasticity occurs when the variances of the error terms are assumed to be a multiplicative function of one or more variables. When variables are not specified in the `het()` option, `hetregress` fits a homoskedastic linear regression model.

Heteroskedasticity arises in a regression when the variances of the error terms are not constant across observations. For example, wages may be heteroskedastic when predicted by age group. While there is little variability in wages among workers in their teens and early 20s, wages among workers in their 50s may vary greatly because of a variety of factors. Heteroskedasticity is often found in time-series data and cross-sectional measurements and is a common issue in econometrics, social science, and many other fields. For more detailed information on how to detect the presence of heteroskedasticity, see [Tests for violation of assumptions](#) in [\[R\] regress postestimation](#).

We can use `hetregress` when the variance is assumed to have a form that is an exponential function of a linear combination of one or more variables. This is known as multiplicative heteroskedasticity and includes most of the useful formulations for variance as special cases. For example, in the special case of groupwise heteroskedasticity, the sample can be divided into groups where each group has a different variance.

A model with multiplicative heteroskedasticity can be written as

$$y_i = \mathbf{x}_i\boldsymbol{\beta} + \epsilon_i; \quad \sigma_i^2 = \exp(\mathbf{z}_i\boldsymbol{\alpha}) \quad (1)$$

where  $y_i$ ,  $i = 1, \dots, n$ , is the dependent variable;  $\mathbf{x}_i = (x_{1i}, x_{2i}, \dots, x_{ki})$  are the  $k$  independent variables that model the mean function; and  $\mathbf{z}_i = (z_{1i}, z_{2i}, \dots, z_{mi})$  are the  $m$  variables that model the variance function.  $\boldsymbol{\beta}$ 's are unknown parameters in the mean function, and  $\boldsymbol{\alpha}$ 's are unknown parameters in the variance function.  $\epsilon_i$ 's are errors that are independent and identically distributed with mean 0 and variance  $\sigma_i^2$ . Groupwise heteroskedasticity is modeled using (1) but where the  $\mathbf{z}_i$ 's are all indicator (dummy) variables for groups.

Harvey (1976) introduced two methods for dealing with multiplicative heteroskedasticity: ML estimation and two-step GLS estimation. By default, `hetregress` fits the multiplicative heteroskedastic regression model using ML. If the `twostep` option is specified, `hetregress` fits the model using the two-step GLS method. The ML estimates are more efficient than those obtained by the GLS estimator if the mean and variance function are correctly specified and the errors are normally distributed. By contrast, the two-step GLS estimates are more robust if the variance function is incorrect or the errors are nonnormal.

If the form of the variance is completely unknown, we may be better off using the OLS estimator instead of the ML and GLS estimators because it remains unbiased. However, we should then use the robust standard errors to correct for heteroskedasticity. Using robust standard errors for the OLS estimator allows us to make appropriate inferences without specifying any form for the variance. We discuss three modifications of the robust variance calculation in [Robust standard errors](#) of [\[R\] regress](#).

If the form of the variance is known and does not contain any unknown parameters, we can use the weighted least-squares estimator, also called the generalized least-squares estimator. For example, we can use weighted least squares to correct for heteroskedasticity if the variance is proportional to one of the regressors. See section 9.5.2 of [Greene \(2018\)](#) for details, and also see [Weighted regression](#) in [R] [regress](#).

[Greene \(2018\)](#) and [Hill, Griffiths, and Lim \(2018\)](#) compare the ML estimator and the GLS estimator with the robust OLS estimator. If the form of the heteroskedasticity is specified correctly, the ML and GLS estimators are more efficient than the robust OLS estimator. However, if the form of the heteroskedasticity is misspecified, the robust OLS estimator may be more efficient than the ML and GLS estimators.

## Maximum likelihood estimation

### ▷ Example 1: Multiplicative heteroskedasticity

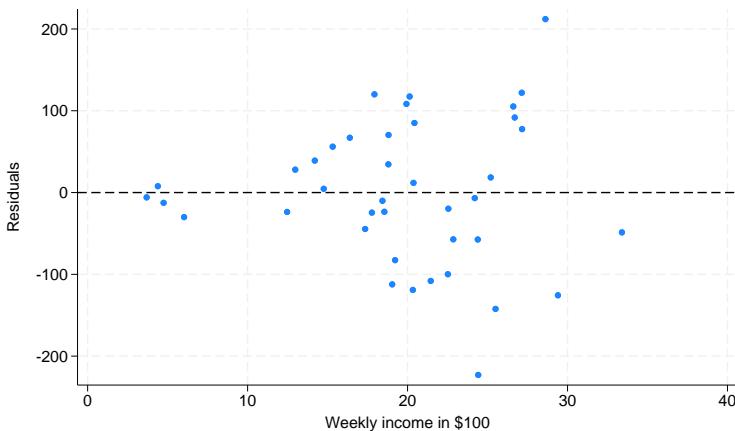

Consider the following dataset from a study of household expenditure on food described in [Hill, Griffiths, and Lim \(2018, chap. 8\)](#). We want to investigate the relationship between average household expenditure on food and household income by fitting a model of weekly food expenditure (`food_exp`) on weekly income (`income`) using OLS.

```
. use https://www.stata-press.com/data/r19/foodexp
(Household expenditure on food)

. regress food_exp income
(output omitted)
```

However, we suspect that the variance for low-income families may be lower than that for high-income families, because low-income families usually have less money to spend on food, while high-income families can choose to spend more or less on food. We plot the least-squares residuals against the value of income by using the `rvpplot` command after `regress`.

```
. rvpplot income, yline(0)
```

The graph confirms our suspicions about a relationship between income and the residuals. We believe that the variance is some power function of income. Therefore, we fit a multiplicative heteroskedastic regression model. The model for each observation is

$$\text{food\_exp}_i = \beta_0 + \beta_1 \times \text{income}_i + \epsilon_i$$

and the variance function can be written as

$$\sigma_i^2 = \sigma^2 \times \text{income}_i^\gamma$$

where  $\gamma$  is an unknown parameter of the variance function. To ensure that we will get positive values for the variance  $\sigma_i^2$  for all possible values of the unknown parameter  $\gamma$ , we rewrite this function so that  $\sigma_i^2$  is an exponential function of a linear combination of  $\ln(\text{income}_i)$  and a constant term:

$$\sigma_i^2 = \exp\{\alpha_0 + \alpha_1 \times \ln(\text{income}_i)\}$$

where  $\alpha_0 = \ln(\sigma^2)$  and  $\alpha_1 = \gamma$ .

To fit this model using `hetregress`, we first create a variable that contains the logarithm of income (`logincome`) and use it in the `het()` option to model the variance function. The constant term in the variance function is always assumed.

```
. generate double logincome = ln(income)
. hetregress food_exp income, het(logincome)
Fitting full model:
Iteration 0: Log likelihood = -227.889
Iteration 1: Log likelihood = -226.61039
Iteration 2: Log likelihood = -225.72188
Iteration 3: Log likelihood = -225.71519
Iteration 4: Log likelihood = -225.71519
Heteroskedastic linear regression Number of obs = 40
ML estimation Wald chi2(1) = 135.11
Log likelihood = -225.7152 Prob > chi2 = 0.0000
```

| food_exp  | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-----------|-------------|-----------|-------|-------|----------------------|----------|
| food_exp  |             |           |       |       |                      |          |
| income    | 10.63444    | .9148876  | 11.62 | 0.000 | 8.841295             | 12.42759 |
| _cons     | 76.07294    | 7.369143  | 10.32 | 0.000 | 61.62969             | 90.5162  |
| lnsigma2  |             |           |       |       |                      |          |
| logincome | 2.769762    | .4481606  | 6.18  | 0.000 | 1.891383             | 3.648141 |
| _cons     | .4684052    | 1.310337  | 0.36  | 0.721 | -2.099809            | 3.036619 |

```
LR test of lnsigma2=0: chi2(1) = 19.59 Prob > chi2 = 0.0000
```

The LR test at the bottom of the output is a test for the parameters of the variance function. The  $\chi^2(1)$  statistic of 19.59 is significant, indicating that heteroskedasticity is present. If we had preferred the Wald test for heteroskedasticity instead of the LR test, we would have specified the `waldhet` option.

In addition to the estimated parameters for the mean function (under `food_exp`), `hetregress` reports estimated parameters and test statistics for the variance function. The significant  $z$  statistic for `logincome` also suggests the presence of heteroskedasticity. Relating the output back to our model,  $\exp(0.47) \approx 1.60$  is our estimate of  $\sigma^2$ . The coefficient for `logincome` is 2.77. This is our estimate of  $\gamma$ , and it can be interpreted as the multiplicative factor of the variance associated with income.

We can obtain more formal results by using `nlcom`:

```
. nlcom (sigma2: exp(_b[lsigma2:_cons]))
 sigma2: exp(_b[lsigma2:_cons])
```

| food_exp | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|----------|-------------|-----------|------|-------|----------------------|----------|
| sigma2   | 1.597445    | 2.093191  | 0.76 | 0.445 | -2.505135            | 5.700024 |

Here `sigma2` refers to  $\sigma^2$  in the variance function given [above](#).

## Two-step GLS estimation

### ▷ Example 2: Groupwise heteroskedasticity

Here we will use a dataset of 725 faculty members' salaries described in [DeMaris \(2004\)](#) to determine whether there is evidence of a difference in salaries between male faculty and female faculty. In addition to `sex` (`female`), other variables that might affect the salaries are prior experience (`priorex`), years in rank (`yrrank`), years at the university (`yrbg`), and marketability of discipline (`salfac`). We will treat `female` as a factor variable and all other variables as continuous variables.

We could fit this model with regress by including main effects and the interaction terms between female and all other variables (by using `factor-variable notation`).

```
. use https://www.stata-press.com/data/r19/salary, clear
(DeMaris (2004) - Faculty salaries)
```

```
. regress salary i.female##(c.priorexp c.yrrank c.yrbg c.salfac)
```

| Source   | SS         | df  | MS         | Number of obs | = | 725    |
|----------|------------|-----|------------|---------------|---|--------|
| Model    | 8.9287e+10 | 9   | 9.9207e+09 | F(9, 715)     | = | 135.23 |
| Residual | 5.2453e+10 | 715 | 73360978.8 | Prob > F      | = | 0.0000 |
|          |            |     |            | R-squared     | = | 0.6299 |
|          |            |     |            | Adj R-squared | = | 0.6253 |
| Total    | 1.4174e+11 | 724 | 195773163  | Root MSE      | = | 8565.1 |

| salary                     | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |           |
|----------------------------|-------------|-----------|-------|-------|----------------------|-----------|
| 1.female                   | 5735.113    | 4987.433  | 1.15  | 0.251 | -4056.65             | 15526.88  |
| priorexp                   | 1042.845    | 82.62092  | 12.62 | 0.000 | 880.6366             | 1205.054  |
| yrrank                     | -47.80904   | 99.85936  | -0.48 | 0.632 | -243.8617            | 148.2436  |
| yrbg                       | 1009.12     | 75.5161   | 13.36 | 0.000 | 860.8607             | 1157.38   |
| salfac                     | 33601.3     | 2531.61   | 13.27 | 0.000 | 28631.02             | 38571.58  |
| female#<br>c.priorexp<br>1 | -662.7972   | 159.6171  | -4.15 | 0.000 | -976.1715            | -349.4228 |
| female#<br>c.yrrank<br>1   | -447.8621   | 218.8695  | -2.05 | 0.041 | -877.5659            | -18.15833 |
| female#c.yrbg<br>1         | 115.4784    | 157.9372  | 0.73  | 0.465 | -194.5976            | 425.5545  |
| female#<br>c.salfac<br>1   | -7618.157   | 5142.204  | -1.48 | 0.139 | -17713.78            | 2477.467  |
| _cons                      | 2137.718    | 2634.266  | 0.81  | 0.417 | -3034.103            | 7309.539  |

However, we believe that the variances differ between female faculty and male faculty. In this case, we will use `estat hettest` to perform the [Breusch and Pagan \(1979\)](#) test for heteroskedasticity. See [Tests for violation of assumptions in \[R\] regress postestimation](#) for more detailed information.

```
. estat hettest i.female
Breusch-Pagan/Cook-Weisberg test for heteroskedasticity
Assumption: Normal error terms
Variable: i.female
HO: Constant variance
chi2(1) = 11.80
Prob > chi2 = 0.0006
```

The results above suggest the presence of heteroskedasticity with respect to sex. This is a case of groupwise heteroskedasticity and can be modeled using `hetregress` by treating the sex variable (`female`) as a factor variable (`i.female`) in the `het()` option.

To obtain an estimate for female faculty of the effect of experience on salary, we can use `lincom`.

```
. lincom priorexp + 1.female#c.priorexp
(1) [salary]priorexp + [salary]1.female#c.priorexp = 0
```

| salary | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|--------|-------------|-----------|------|-------|----------------------|----------|
| (1)    | 380.0481    | 110.8702  | 3.43 | 0.001 | 162.7465             | 597.3497 |

We see that each additional year of experience increases salary by only \$380.05 and that this effect is significant.

We can estimate the effect of each of the other variables on the salaries of female faculty if we wish.

```
. lincom yrrank + 1.female#c.yrrank
(1) [salary]yrrank + [salary]1.female#c.yrrank = 0
```

| salary | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |           |
|--------|-------------|-----------|-------|-------|----------------------|-----------|
| (1)    | -495.6711   | 158.1108  | -3.13 | 0.002 | -805.5627            | -185.7796 |

The effect of `yrrank` is associated with a decrease in salary. The effect is significant for female faculty but not for male faculty.

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|                       |                                                                                                                            |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

`hetregress` (two-step GLS) stores the following in `e()`:

## Scalars

|                        |                                                |
|------------------------|------------------------------------------------|
| <code>e(N)</code>      | number of observations                         |
| <code>e(k)</code>      | number of parameters                           |
| <code>e(df_m)</code>   | model degrees of freedom                       |
| <code>e(chi2)</code>   | $\chi^2$ for mean model test                   |
| <code>e(chi2_c)</code> | $\chi^2$ for heteroskedasticity test           |
| <code>e(p_c)</code>    | <i>p</i> -value for heteroskedasticity test    |
| <code>e(df_m_c)</code> | degrees of freedom for heteroskedasticity test |
| <code>e(p)</code>      | <i>p</i> -value for the mean model test        |
| <code>e(rank)</code>   | rank of <code>e(V)</code>                      |

## Macros

|                          |                                                                                     |
|--------------------------|-------------------------------------------------------------------------------------|
| <code>e(cmd)</code>      | <code>hetregress</code>                                                             |
| <code>e(cmdline)</code>  | command as typed                                                                    |
| <code>e(depvar)</code>   | name of dependent variable                                                          |
| <code>e(title)</code>    | title in estimation output                                                          |
| <code>e(title2)</code>   | secondary title in estimation output                                                |
| <code>e(chi2type)</code> | Wald; type of model $\chi^2$ test                                                   |
| <code>e(chi2_ct)</code>  | Wald; type of heteroskedastic $\chi^2$ test corresponding to <code>e(chi2_c)</code> |

|                 |                                                                |
|-----------------|----------------------------------------------------------------|
| e(vce)          | <i>vcetype</i> specified in <code>vce()</code>                 |
| e(method)       | <code>twostep</code>                                           |
| e(properties)   | <code>b V</code>                                               |
| e(predict)      | program used to implement <code>predict</code>                 |
| e(marginsok)    | predictions allowed by <code>margins</code>                    |
| e(marginsnotok) | predictions disallowed by <code>margins</code>                 |
| e(asbalanced)   | factor variables <code>fvset</code> as <code>asbalanced</code> |
| e(asobserved)   | factor variables <code>fvset</code> as <code>asobserved</code> |
| Matrices        |                                                                |
| e(b)            | coefficient vector                                             |
| e(V)            | variance–covariance matrix of the estimators                   |
| Functions       |                                                                |
| e(sample)       | marks estimation sample                                        |

In addition to the above, the following is stored in `r()`:

|          |                                                                                                                            |
|----------|----------------------------------------------------------------------------------------------------------------------------|
| Matrices |                                                                                                                            |
| r(table) | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r`-class command is run after the estimation command.

## Methods and formulas

Methods and formulas are presented under the following headings:

*Maximum likelihood estimation*  
*Two-step GLS estimation*

### Maximum likelihood estimation

By default, `hetregress` fits a multiplicative heteroskedastic regression using ML estimation. The log-likelihood function is

$$\ln L = \sum_{i=1}^n \frac{w_i}{2} \left\{ \frac{(y_i - \mathbf{x}_i \boldsymbol{\beta})^2}{\exp(\mathbf{z}_i \boldsymbol{\alpha})} - \ln(2\pi) - \mathbf{z}_i \boldsymbol{\alpha} \right\}$$

where  $y_i$ ,  $i = 1, \dots, n$ , is the dependent variable;  $\mathbf{x}_i = (x_{1i}, x_{2i}, \dots, x_{ki})$  are the  $k$  independent variables that model the mean function;  $\mathbf{z}_i = (z_{1i}, z_{2i}, \dots, z_{mi})$  are the  $m$  variables that model the variance function; and  $w_i$  are the weights.  $\boldsymbol{\beta}$  is a column vector of unknown parameters in the mean function, and  $\boldsymbol{\alpha}$  is a column vector of unknown parameters in the variance function. The GLS estimates  $\widehat{\boldsymbol{\beta}}_{\text{GLS}}$  and  $\widehat{\boldsymbol{\alpha}}_{\text{GLS}}$  (described below) are used as the initial values in ML estimation. The  $\ln L$  function is maximized as described in [R] **Maximize**.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] **\_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`hetregress` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **Variance estimation**.

## Two-step GLS estimation

hetregress uses two-step GLS estimation when the `twostep` option is specified. Harvey (1976) describes the procedure in detail, but here are the main steps.

1. Use OLS to estimate regression coefficients  $\beta$  and compute residuals  $\mathbf{e}_i, i = 1, \dots, n$ .
2. Use OLS to regress the log-squared residuals,  $\ln(\mathbf{e}_i^2)$ , on  $\mathbf{z}$  and estimate  $\alpha$ .
3. Perform correction for the OLS estimates of  $\alpha$  to obtain  $\hat{\alpha}_c$  and their covariance matrix based on Harvey (1976).
4. Compute  $\hat{\sigma}_i^2 = \exp(\mathbf{z}_i \hat{\alpha}_c), i = 1, \dots, n$ .
5. Refit the original regression model using  $\hat{\sigma}_i^2$ 's as weights to obtain the GLS estimates  $\hat{\alpha}_{\text{GLS}}$  and  $\hat{\beta}_{\text{GLS}}$ .

## Postestimation commands

The following postestimation commands are available after `hetregress`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| * <code>estat ic</code>      | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| * <code>estat (svy)</code>   | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| † <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| † <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| *† <code>lrtest</code>       | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | linear predictions and their SEs, etc.                                                                                                  |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| * <code>suest</code>         | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`estat ic`, `estat (svy)`, `lrtest`, and `suest` are not appropriate after `hetregress`, `twostep`.

†`forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as linear predictions, standard errors, and standard deviations.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

*After ML or two-step*

```
predict [type] newvar [if] [in] [, statistic]
```

*After ML*

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

---

Main

|                    |                                         |
|--------------------|-----------------------------------------|
| <code>xb</code>    | linear prediction; the default          |
| <code>stdp</code>  | standard error of the linear prediction |
| <code>sigma</code> | standard deviation of the error term    |

---

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard errors of the linear prediction.

`sigma` calculates the standard deviations of the error term.

`scores` calculates equation-level score variables.

The first new variable will contain the derivative of the log likelihood with respect to the regression equation,  $\partial \ln L / \partial (\mathbf{x}_i \boldsymbol{\beta})$ .

The second new variable will contain the derivative of the log likelihood with respect to the scale equation (`lnsigma2`),  $\partial \ln L / \partial (\mathbf{z}_i \boldsymbol{\alpha})$ .

## margins

### Description for margins

`margins` estimates margins of response for linear predictions and of standard deviations.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```

margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]

```

| <i>statistic</i>   | Description                           |
|--------------------|---------------------------------------|
| <code>xb</code>    | linear prediction; the default        |
| <code>stdp</code>  | not allowed with <code>margins</code> |
| <code>sigma</code> | standard deviation of the error term  |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

### Remarks and examples

Once you have fit a heteroskedastic regression model, you can use the `predict` command to obtain the predicted values both for the estimation sample and for other samples; see [U] [20 Estimation and postestimation commands](#) and [R] [predict](#). `predict` without arguments calculates the linear prediction from the fitted model  $\mathbf{x}_i\mathbf{b}$ , where  $\mathbf{x}_i$  are the independent variables in the  $j$ th observation and  $\mathbf{b}$  is the estimated parameter vector for the mean model. With the `stdp` option, `predict` calculates the standard error of the linear prediction. With the `sigma` option, `predict` calculates the predicted standard deviations of the error term,  $\hat{\sigma}_j = \exp(0.5 \times \mathbf{z}_i\mathbf{a})$ , where  $\mathbf{g}$  is the estimated parameter vector for the variance model.

▷ Example 1: Predicting heteroskedastic standard deviation

We can use `predict` to compute the predicted values of the standard deviations for female and male faculty based on the model from [example 2](#) in [R] `hetregress`.

```
. use https://www.stata-press.com/data/r19/salary
(DeMaris (2004) - Faculty salaries)
. hetregress salary i.female##(c.priorexp c.yrrank c.yrbg c.salfac),
> het(i.female) twostep
(output omitted)
. predict sigma, sigma
. tabulate female, summarize(sigma)
```

| 1 = female;<br>0 = male | Summary of Heteroskedastic standard deviation |           |       |
|-------------------------|-----------------------------------------------|-----------|-------|
|                         | Mean                                          | Std. dev. | Freq. |
| 0                       | 7741.8481                                     | 0         | 511   |
| 1                       | 5828.6973                                     | 0         | 214   |
| Total                   | 7177.1388                                     | 873.22924 | 725   |

The predicted standard deviation for male faculty is  $7742/5829 \approx 1.3$  times the size for female faculty. We could have obtained the same results using `margins` with the `predict(sigma)` option.

▷ Example 2: Marginal means

We can use `margins` to compute the adjusted mean salary for male and female faculty when other factors are fixed at their means:

```
. margins female, atmeans
Adjusted predictions Number of obs = 725
Model VCE: Conventional
Expression: Linear prediction, predict()
At: priorexp = 2.89931 (mean)
 yrrank = 7.397241 (mean)
 yrbg = 12.52966 (mean)
 salfac = .9399862 (mean)
```

|        | Delta-method |           |        |       |                      |
|--------|--------------|-----------|--------|-------|----------------------|
|        | Margin       | std. err. | z      | P> z  | [95% conf. interval] |
| female |              |           |        |       |                      |
| 0      | 49036.29     | 420.3711  | 116.65 | 0.000 | 48212.37 49860.2     |
| 1      | 43822.74     | 569.9368  | 76.89  | 0.000 | 42705.69 44939.8     |

If everyone in the population were male faculty while holding all other factors at their mean values, the average salary would be \$49,036. If, instead, everyone were female faculty, the average salary would be \$43,823.

[U] 20 Estimation and postestimation commands

[Description](#)  
[References](#)[Quick start](#)  
[Also see](#)[Menu](#)[Syntax](#)[Options](#)[Remarks and examples](#)

## Description

`histogram` draws histograms of *varname*, which is assumed to be the name of a continuous variable unless the `discrete` option is specified.

`hist` is a synonym for `histogram`.

## Quick start

Histogram of `v1`

```
histogram v1
```

Add a normal density curve to the graph

```
histogram v1, normal
```

Add a kernel density estimate to the graph

```
histogram v1, normal kdensity
```

Add “My Title” as the title of the graph

```
histogram v1, normal kdensity title("My Title")
```

Specify the number of bins as 10

```
histogram v1, bins(10)
```

Specify the width of the bins as 2

```
histogram v1, width(2)
```

Specify that `v2` should be treated as discrete

```
histogram v2, discrete
```

Same as above, but with narrower bars and space between the bars

```
histogram v2, discrete barwidth(.8)
```

Add labels to the bars on the *x* axis

```
histogram v2, discrete barwidth(.8) xlabel(1 "Category 1" ///
2 "Category 2" 3 "Category 3" 4 "Category 4")
```

Show frequencies on the *y* axis

```
histogram v1, frequency
```

Show percentages on the *y* axis

```
histogram v1, percent
```

Produce histograms for each value of categorical variable `catvar`

```
histogram v1, by(catvar)
```

Same as above, but with histograms arranged in a single column

```
histogram v1, by(cvar, cols(1))
```

## Menu

Graphics > Histogram

## Syntax

```
histogram varname [if] [in] [weight] [, [continuous_opts | discrete_opts] options]
```

### *continuous\_opts*

### Description

| <u>addplot</u> ( <i>plot</i> ) | add other plots to the histogram |
|--------------------------------|----------------------------------|

Y axis, X axis, Titles, Legend, Overall, By

|                       |                                                       |
|-----------------------|-------------------------------------------------------|
| <i>twoway_options</i> | any options documented in [G-3] <i>twoway_options</i> |
|-----------------------|-------------------------------------------------------|

`fweights` are allowed; see [U] 11.1.6 `weight`.

## Options

Options are presented under the following headings:

- Options for use in the continuous case*
- Options for use in the discrete case*
- Options for use in the continuous and discrete cases*

### Options for use in the continuous case

Main

`bins(#)` and `width(#)` are alternatives. They specify how the data are to be aggregated into bins: `bins()` by specifying the number of bins (from which the width can be derived) and `width()` by specifying the bin width (from which the number of bins can be derived).

If neither option is specified, results are the same as if `bins( $k$ )` had been specified, where

$$k = \min\{\text{sqrt}(N), 10 \ln(N)/\ln(10)\}$$

and where  $N$  is the (weighted) number of observations.

`start(#)` specifies the theoretical minimum of *varname*. The default is `start( $m$ )`, where  $m$  is the observed minimum value of *varname*.

Specify `start()` when you are concerned about sparse data, for instance, if you know that *varname* can have a value of 0, but you are concerned that 0 may not be observed.

`start(#)`, if specified, must be less than or equal to  $m$ , or else an error will be issued.

### Options for use in the discrete case

Main

`discrete` specifies that *varname* is discrete and that you want each unique value of *varname* to have its own bin (bar of histogram).

`width(#)` is rarely specified in the discrete case; it specifies the width of the bins. The default is `width( $d$ )`, where  $d$  is the observed minimum difference between the unique values of *varname*.

Specify `width()` if you are concerned that your data are sparse. For example, in theory *varname* could take on the values, say, 1, 2, 3, ..., 9, but because of the sparseness, perhaps only the values 2, 4, 7, and 8 are observed. Here the default width calculation would produce `width(2)`, and you would want to specify `width(1)`.

`start(#)` is also rarely specified in the discrete case; it specifies the theoretical minimum value of *varname*. The default is `start( $m$ )`, where  $m$  is the observed minimum value.

As with `width()`, specify `start(#)` if you are concerned that your data are sparse. In the previous example, you might also want to specify `start(1)`. `start()` does nothing more than add white space to the left side of the graph.

The value of  $\#$  in `start()` must be less than or equal to  $m$ , or an error will be issued.

## Options for use in the continuous and discrete cases

### Main

`density`, `fraction`, `frequency`, and `percent` specify whether you want the histogram scaled to density units, fractional units, frequencies, or percentages. `density` is the default.

`density` scales the height of the bars so that the sum of their areas equals 1.

`fraction` scales the height of the bars so that the sum of their heights equals 1.

`frequency` scales the height of the bars so that each bar's height is equal to the number of observations in the category. Thus the sum of the heights is equal to the total number of observations.

`percent` scales the height of the bars so that the sum of their heights equals 100.

`bar_options` are any of the options allowed by `graph twoway bar`; see [G-2] [graph twoway bar](#).

One of the most useful `bar_options` is `barwidth(#)`, which specifies the width of the bars in `varname` units. By default, `histogram` draws the bars so that adjacent bars just touch. If you want gaps between the bars, do not specify `histogram`'s `width()` option—which would change how the histogram is calculated—but specify the `bar_option` `barwidth()` or the `histogram` option `gap`, both of which affect only how the bar is rendered.

The `bar_option` `horizontal` cannot be used with the `addlabels` option.

`binrescale` specifies that bin size and plot range be recalculated for each group when `by()` is specified. If `normal` is specified, the mean and standard deviation of each overlaid normal density plot are recalculated in each group. Similarly, if `kdensity` is specified, the scaling of the overlaid kernel density plot is recalculated in each group.

`addlabels` specifies that the top of each bar be labeled with the density, fraction, or frequency, as determined by the `density`, `fraction`, and `frequency` options.

`addlabopts(marker_label_options)` specifies how to render the labels atop the bars. See [G-3] [marker\\_label\\_options](#). Do not specify the `marker_label_option` `mlabel(varname)`, which specifies the variable to be used; this is specified for you by `histogram`.

`addlabopts()` will accept more options than those documented in [G-3] [marker\\_label\\_options](#). All options allowed by `twoway scatter` are also allowed by `addlabopts()`; see [G-2] [graph twoway scatter](#). One particularly useful option is `yvarformat()`; see [G-3] [advanced\\_options](#).

### Density plots

`normal` specifies that the histogram be overlaid with an appropriately scaled normal density. The normal will have the same mean and standard deviation as the data.

`normopts(line_options)` specifies details about the rendition of the normal curve, such as the color and style of line used. See [G-2] [graph twoway line](#).

`kdensity` specifies that the histogram be overlaid with an appropriately scaled kernel density estimate of the density. By default, the estimate will be produced using the Epanechnikov kernel with an “optimal” half-width. This default corresponds to the default of `kdensity`; see [R] [kdensity](#). How the estimate is produced can be controlled using the `kdenopts()` option described below.

`kdenopts` (*kdensity\_options*) specifies details about how the kernel density estimate is to be produced along with details about the rendition of the resulting curve, such as the color and style of line used; see [G-2] [graph twoway kdensity](#). The kernel density estimate is described in [R] [kdensity](#). As an example, if you wanted to produce kernel density estimates by using the Gaussian kernel with optimal half-width, you would specify `kdenopts(gauss)` and if you also wanted a half-width of 5, you would specify `kdenopts(gauss width(5))`.

Add plots

`addplot` (*plot*) allows adding more graph twoway plots to the graph; see [G-3] [addplot\\_option](#).

Y axis, X axis, Titles, Legend, Overall, By

*twoway\_options* are any of the options documented in [G-3] [twoway\\_options](#). This includes, most importantly, options for titling the graph (see [G-3] [title\\_options](#)), options for saving the graph to disk (see [G-3] [saving\\_option](#)), and the `by()` option, which will allow you to simultaneously graph histograms for different subsets of the data (see [G-3] [by\\_option](#)).

## Remarks and examples

Remarks are presented under the following headings:

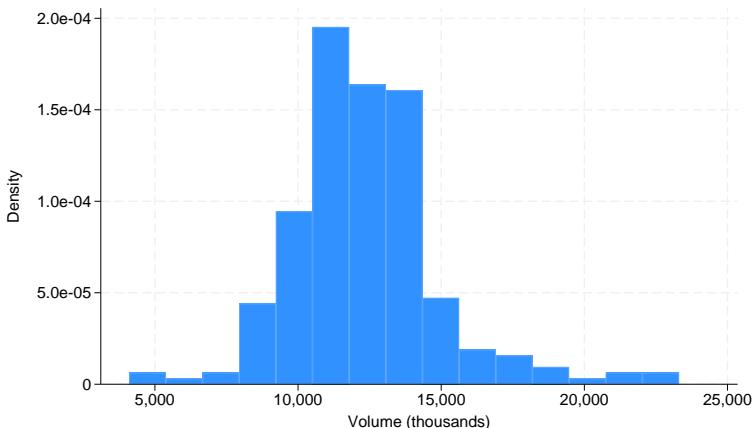

- [Histograms of continuous variables](#)
- [Overlaying normal and kernel density estimates](#)
- [Histograms of discrete variables](#)
- [Use with by\(\)](#)
- [Video example](#)

For an example of editing a histogram with the Graph Editor, see [Pollock \(2011, 29–31\)](#).

## Histograms of continuous variables

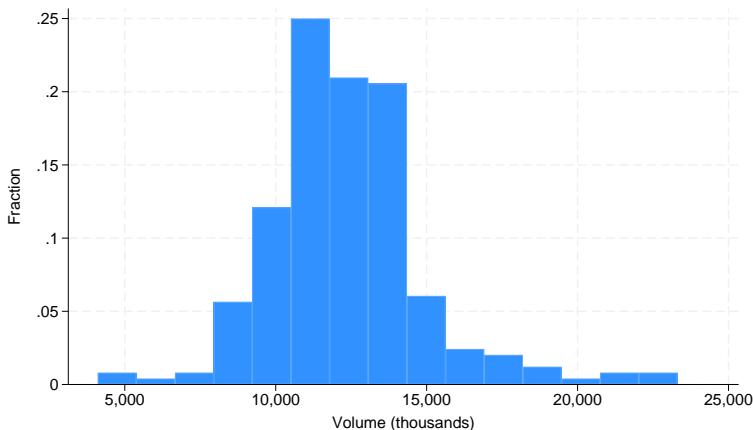

`histogram` assumes that the variable is continuous, so you need type only `histogram` followed by the variable name:

```
. use https://www.stata-press.com/data/r19/sp500
(S&P 500)
. histogram volume
(bin=15, start=4103, width=1280.3533)
```

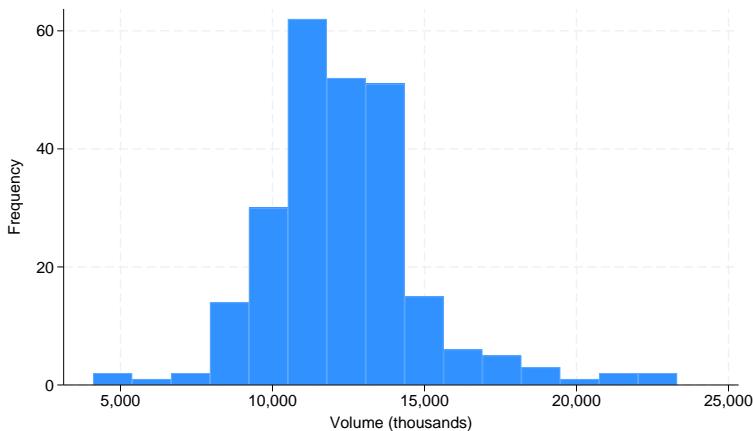

The small values reported for density on the  $y$  axis are correct; if you added up the area of the bars, you would get 1. Nevertheless, many people are used to seeing histograms scaled so that the bar heights sum to 1,

```
. histogram volume, fraction
(bin=15, start=4103, width=1280.3533)
```

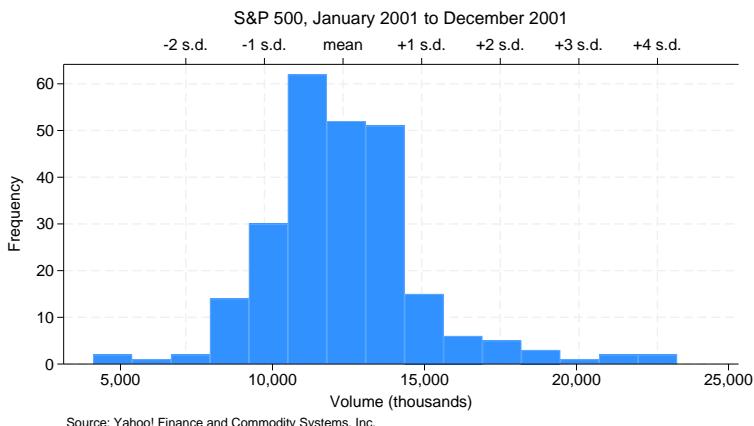

and others are used to seeing histograms so that the bar height reflects the number of observations,

```
. histogram volume, frequency
(bin=15, start=4103, width=1280.3533)
```

Regardless of the scale you prefer, you can specify other options to make the graph look more impressive:

```
. summarize volume
+-----+-----+-----+-----+-----+
| Variable | Obs | Mean | Std. dev. | Min | Max |
+-----+-----+-----+-----+-----+
| volume | 248 | 12320.68 | 2585.929 | 4103 | 23308.3 |
+-----+-----+-----+-----+-----+
. histogram volume, freq
> xaxis(1 2)
> ylabel(0(10)60)
> xlabel(12321 "mean"
> 9735 "-1 s.d."
> 14907 "+1 s.d."
> 7149 "-2 s.d."
> 17493 "+2 s.d."
> 20078 "+3 s.d."
> 22664 "+4 s.d."
>
> , axis(2) grid)
> xlabel(, axis(1) nogrid)
> xttitle("", axis(2))
> subtitle("S&P 500, January 2001 to December 2001")
> note("Source: Yahoo! Finance and Commodity Systems, Inc.")
(bin=15, start=4103, width=1280.3533)
```

For an explanation of the `xaxis()` option—it created the upper and lower  $x$  axis—see [G-3] [axis\\_choice\\_options](#). For an explanation of the `ylabel()` and `xlabel()` options, see [G-3] [axis\\_label\\_options](#). For an explanation of the `subtitle()` and `note()` options, see [G-3] [title\\_options](#).

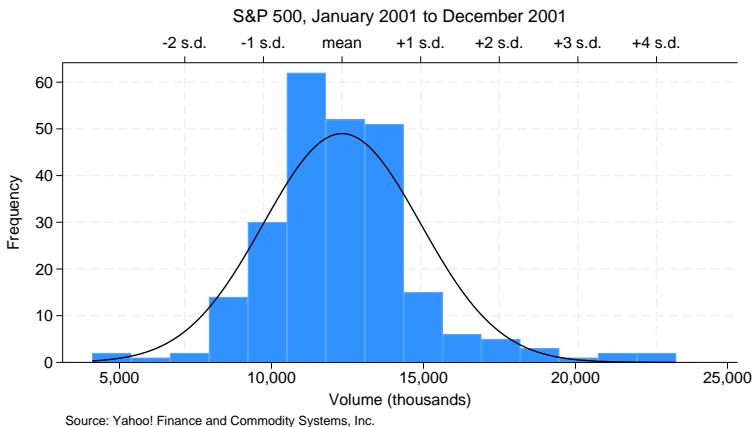

## Overlaying normal and kernel density estimates

Specifying `normal` will overlay a normal density over the histogram. It would be enough to type

```
. histogram volume, normal
```

but we will add the option to our more impressive rendition:

```
. summarize volume
+-----+-----+-----+-----+-----+
| Variable | Obs | Mean | Std. dev. | Min | Max |
+-----+-----+-----+-----+-----+
| volume | 248 | 12320.68 | 2585.929 | 4103 | 23308.3 |
+-----+-----+-----+-----+-----+
. histogram volume, freq normal
> xaxis(1 2)
> ylabel(0(10)60)
> xlabel(12321 "mean"
> 9735 "-1 s.d."
> 14907 "+1 s.d."
> 7149 "-2 s.d."
> 17493 "+2 s.d."
> 20078 "+3 s.d."
> 22664 "+4 s.d."
>
> , axis(2) grid
> xlabel(, axis(1) nogrid)
> xtitle("", axis(2))
> subtitle("S&P 500, January 2001 to December 2001")
> note("Source: Yahoo! Finance and Commodity Systems, Inc.")
(bin=15, start=4103, width=1280.3533)
```

If we instead wanted to overlay a kernel density estimate, we could specify `kdensity` in place of `normal`.

## Histograms of discrete variables

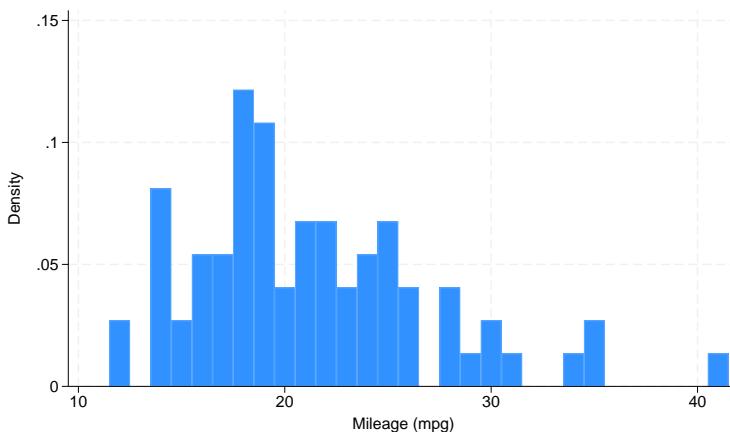

Specify histogram's discrete option when you wish to treat the data as discrete—when you wish each unique value of the variable to be assigned its own bin. For instance, in the automobile data, mpg is a continuous variable, but the mileage ratings have been measured to integer precision. If we were to type

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. histogram mpg
(bin=8, start=12, width=3.625)
```

mpg would be treated as continuous and categorized into eight bins by the default number-of-bins calculation, which is based on the number of observations, 74.

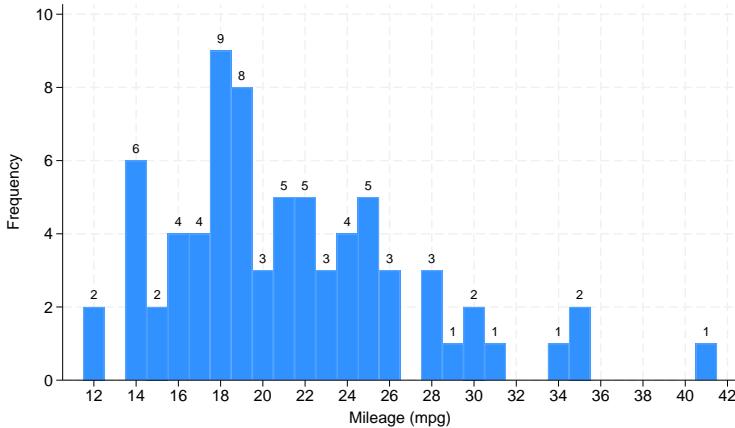

Adding the discrete option makes a histogram with a bin for each of the 21 unique values.

```
. histogram mpg, discrete
(start=12, width=1)
```

Just as in the continuous case, the  $y$  axis was reported in density, and we could specify the fraction or frequency options if we wanted it to be reported differently. Below, we specify frequency, we specify `addlabels` to add a report of frequencies printed above the bars, and we specify `xlabel(12(2)42)` to label the values 12, 14, ..., 42 on the  $x$  axis:

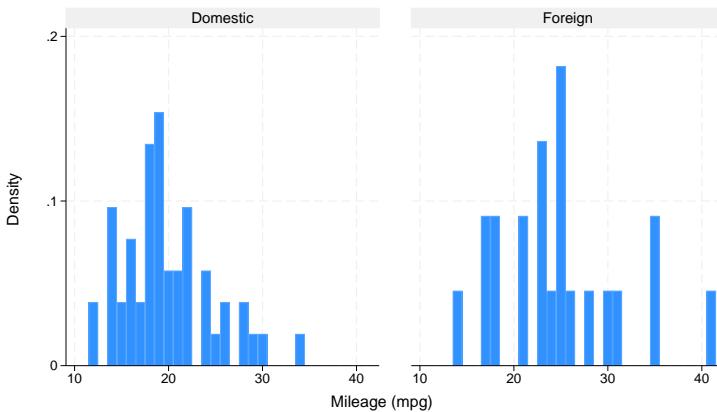

```
. histogram mpg, discrete freq addlabels xlabel(12(2)42)
(start=12, width=1)
```

### Use with by()

`histogram` may be used with `graph twoway's by()`; for example,

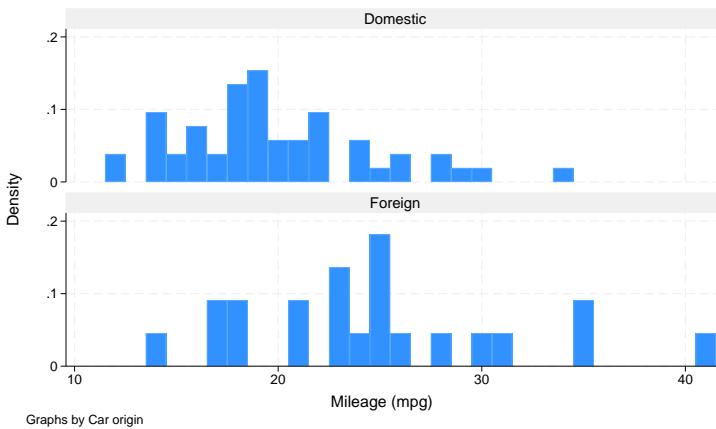

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. histogram mpg, discrete by(foreign)
```

Graphs by Car origin

Here results would be easier to compare if the graphs were presented in one column:

```
. histogram mpg, discrete by(foreign, col(1))
```

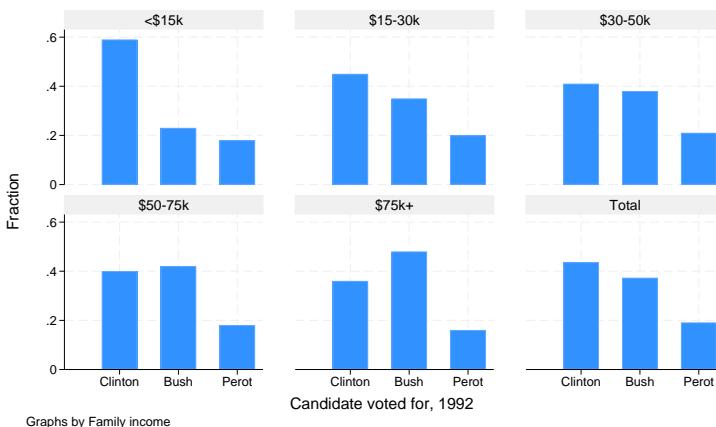

col(1) is a by() suboption—see [G-3] *by\_option*—and there are other useful suboptions, such as total, which will add an overall total histogram. total is a suboption of by(), not an option of histogram, so you would type

```
. histogram mpg, discrete by(foreign, total)
```

and not histogram mpg, discrete by(foreign) total.

As another example, [Lipset \(1993\)](#) reprinted data from the *New York Times* (November 5, 1992) collected by the Voter Research and Surveys based on questionnaires completed by 15,490 US presidential voters from 300 polling places on election day in 1992.

```
. sysuse voter, clear
(1992 US presidential voters)
. histogram candi [fweight=pop], discrete fraction by(inc, total)
> gap(40) xlabel(2 3 4, valuelabel)
```

We specified `gap(40)` to reduce the width of the bars by 40%. We also used `xlabel()`'s `valueLabel` suboption, which caused our bars to be labeled “Clinton”, “Bush”, and “Perot”, rather than 2, 3, and 4; see [G-3] *axis\_label\_options*.

## Description

This entry discusses a statistical issue that arises when using the Bayesian (BIC), consistent Akaike's (CAIC), and corrected Akaike's (AICc) information criteria to compare models.

Stata calculates BIC, CAIC, and AICc using  $N = e(N)$ , unless `e(N_lic)` has been set; in that instance, it uses  $N = e(N\_lic)$ . For example, choice-model `cm` commands set `e(N_lic)` to the number of cases because these commands use a data arrangement in which multiple Stata observations represent a single statistical observation, which is called a case.

Sometimes, it would be better if a different  $N$  than  $e(N)$  were used. Commands that calculate BIC, CAIC, and AICc have an `n()` option, allowing you to specify the  $N$  to be used.

In summary,

1. if you are comparing results estimated by the same estimation command, using the default BIC, CAIC, or AICc calculation is probably fine. There is an issue, but most researchers would ignore it.
2. if you are comparing results estimated by different estimation commands, you need to be on your guard.
  - (a) If the different estimation commands share the same definitions of observations, independence, and the like, you are back to case 1.
  - (b) If they differ in these regards, you need to think about the value of  $N$  that should be used. For example, `logit` and `xtlogit` differ in that the former assumes independent observations and the latter, independent panels.
  - (c) If estimation commands differ in the events being used over which the likelihood function is calculated, the information criteria may not be comparable at all. We say information *criteria* because this would apply equally to the Akaike information criterion (AIC) and its possible extensions AICc and CAIC, as well as to the BIC. For instance, `streg` and `stcox` produce such incomparable results. The events used by `streg` are the actual survival times, whereas the events used by `stcox` are failures within risk pools, conditional on the times at which failures occurred.

## Remarks and examples

Remarks are presented under the following headings:

*Background*

*The problem of determining  $N$*

*The problem of conformable likelihoods*

*The first problem does not arise with AIC; the second problem does*

*Calculating BIC, AICc, and CAIC correctly*

## Background

The AIC and the BIC are two popular measures for comparing maximum likelihood models. AIC and BIC are defined as

$$\text{AIC} = -2 \ln L + 2k$$

$$\text{BIC} = -2 \ln L + k \ln N$$

where

$\ln L$  = maximized log-likelihood

$k$  = number of parameters estimated

$N$  = number of observations

However, when sample size is small, AIC is biased, and [Burnham and Anderson \(2002\)](#) suggest to use AICc,

$$\text{AICc} = \text{AIC} + \frac{2k(k+1)}{N-k-1}$$

CAIC is a consistent version of AIC and was proposed in [Bozdogan \(1987\)](#),

$$\text{CAIC} = -2 \ln L + k(\ln N + 1)$$

All four information criteria—AIC, BIC, CAIC, and AICc—can be viewed as measures that combine fit and complexity. Fit is measured negatively by  $-2 \ln L$ ; the larger the value, the worse the fit. Complexity is measured positively, for example, by  $2k$  (AIC) or  $k \ln N$  (BIC).

Given two models fit on the same data, the model with the smaller value of the information criterion is considered to be better.

There is substantial literature on these measures: see [Akaike \(1974\)](#); [Raftery \(1995\)](#); [Sakamoto, Ishiguro, and Kitagawa \(1986\)](#); [Schwarz \(1978\)](#); [Burnham and Anderson \(2002\)](#); and [Hurvich and Tsai \(1989\)](#).

When Stata calculates the above measures, it uses the rank of  $e(V)$  for  $k$ , and it uses  $e(N)$  for  $N$ .  $e(V)$  and  $e(N)$  are Stata notation for results stored by the estimation command.  $e(V)$  is the variance–covariance matrix of the estimated parameters, and  $e(N)$  is the number of observations in the dataset used in calculating the result.

## The problem of determining $N$

The difference between AIC and the other three information criteria is that AIC uses the constant 2 to weight  $k$ , whereas the complexity term for BIC, CAIC, and AICc depends on  $N$ .

Determining what value of  $N$  should be used is problematic. Despite appearances, the definition “ $N$  is the number of observations” is not easy to make operational.  $N$  does not appear in the likelihood function itself,  $N$  is not the output of a standard statistical formula, and what is an observation is often subjective.

## ▷ Example 1

Often what is meant by  $N$  is obvious. Consider a simple logit model. What is meant by  $N$  is the number of observations that is statistically independent and that corresponds to  $M$ , the number of observations in the dataset used in the calculation. We will write  $N = M$ .

But now assume that the same dataset has a grouping variable and the data are thought to be clustered within group. To keep the problem simple, let's pretend that there are  $G$  groups and  $m$  observations within group, so that  $M = G \times m$ . Because you are worried about intragroup correlation, you fit your model with `xtlogit`, grouping on the grouping variable. Now, you wish to calculate BIC. What is the  $N$  that should be used?  $N = M$  or  $N = G$ ?

That is a deep question. If the observations really are independent, then you should use  $N = M$ . If the observations within group are not just correlated but are duplicates of one another, and they had to be so, then you should use  $N = G$  (Kass and Raftery 1995). Between those two extremes, you should probably use a number between  $N$  and  $G$ , but determining what that number should be from measured correlations is difficult. Using  $N = M$  is conservative in that, if anything, it overweights complexity. Conservativeness, however, is subjective, too: using  $N = G$  could be considered more conservative in that fewer constraints are being placed on the data.

When the estimated correlation is high, our reaction would be that using  $N = G$  is probably more reasonable. Our first reaction, however, would be that using BIC to compare models is probably a misuse of the measure.

Stata uses  $N = M$ . An informal survey of web-based literature suggests that  $N = M$  is the popular choice.

There is another reason, not so good, to choose  $N = M$ . It makes across-model comparisons more likely to be valid when performed without thinking about the issue. Say that you wish to compare the `logit` and `xtlogit` results. Thus, you need to calculate

$$\text{BIC}_p = -2 \ln L_p + k \ln N_p$$

$$\text{BIC}_x = -2 \ln L_x + k \ln N_x$$

Whatever  $N$  you use, you must use the same  $N$  in both formulas. Stata's choice of  $N = M$  at least meets that test.

◀

## ▷ Example 2

In the above example, using  $N = M$  is reasonable. Now, let's look at when using  $N = M$  is wrong, even if popular.

Consider a model fit by `stcox`. Using  $N = M$  is certainly wrong if for no other reason than  $M$  is not even a well-defined number. The same data can be represented by different datasets with different numbers of observations. For example, in one dataset, there might be one observation per subject. In another, the same subjects could have two records each, the first recording the first half of the time at risk and the second recording the remaining part. All statistics calculated by Stata on either dataset would be the same, but  $M$  would be different.

Deciding on the right definition, however, is difficult. Viewed one way,  $N$  in the Cox regression case should be the number of risk pools,  $R$ , because the Cox regression calculation is made on the basis of the independent risk pools. Viewed another way,  $N$  should be the number of subjects,  $N_{\text{subj}}$ , because, even though the likelihood function is based on risk pools, the parameters estimated are at the subject level.

You can decide which argument you prefer.

For parametric survival models, in single-record data,  $N = M$  is unambiguously correct. For multi-record data, there is an argument for  $N = M$  and for  $N = N_{\text{subj}}$ .

## The problem of conformable likelihoods

The problem of conformable likelihoods does not concern  $N$ . Researchers sometimes use information criteria such as BIC and AIC to make comparisons across models. For that to be valid, the likelihoods must be conformable; that is, the likelihoods must all measure the same thing.

It is common to think of the likelihood function as the  $\Pr(\text{data} \mid \text{parameters})$ , but in fact, the likelihood is

$$\Pr(\text{particular events in the data} \mid \text{parameters})$$

You must ensure that the events are the same.

For instance, they are not the same in the semiparametric Cox regression and the various parametric survival models. In Cox regression, the events are, at each failure time, that the subjects observed to fail in fact failed, given that failures occurred at those times. In the parametric models, the events are that each subject failed exactly when the subject was observed to fail.

The formula for AIC, AICc, CAIC, and BIC can be written as

$$\text{measure} = -2 \ln L + \text{complexity}$$

When you are comparing models, if the likelihoods are measuring different events, even if the models obtain estimates of the same parameters, differences in the information measures are irrelevant.

## The first problem does not arise with AIC; the second problem does

Regardless of model, the problem of defining  $N$  never arises with AIC because  $N$  is not used in the AIC calculation. AIC uses a constant 2 to weight complexity as measured by  $k$ , rather than  $\ln N$ .

However, for all four information criteria—AIC, AICc, CAIC, and BIC—the likelihood functions must be conformable; that is, they must be measuring the same event.

## Calculating BIC, AICc, and CAIC correctly

When using BIC, AICc, or CAIC to compare results, and especially when using them to compare results from different models, you should think carefully about how  $N$  should be defined. Then, specify that number by using the `n()` option:

```
. estimates stats full sub, all n(74)
```

```
Information criteria
```

| Model | N  | ll(null)  | ll(model) | df |
|-------|----|-----------|-----------|----|
| full  | 74 | -45.03321 | -20.59083 | 4  |
| sub   | 74 | -45.03321 | -27.17516 | 3  |

| Model | AIC      | BIC      | AICc     | CAIC     |
|-------|----------|----------|----------|----------|
| full  | 49.18167 | 58.39793 | 49.76138 | 62.39793 |
| sub   | 60.35031 | 67.26251 | 60.69317 | 70.26251 |

Legend: AIC is Akaike's information criterion.

BIC is Bayesian information criterion.

AICc is corrected Akaike's information criterion.

CAIC is consistent Akaike's information criterion.

Both `estimates stats` and `estat ic` allow the `n()` option; see [\[R\] estimates stats](#) and [\[R\] estat ic](#).

## Methods and formulas

AIC, BIC, CAIC, and AICc are defined as

$$\text{AIC} = -2 \ln L + 2k$$

$$\text{BIC} = -2 \ln L + k \ln N$$

$$\text{CAIC} = -2 \ln L + k(\ln N + 1)$$

$$\text{AICc} = \text{AIC} + \frac{2k(k+1)}{N-k-1}$$

where  $\ln L$  is the maximized log-likelihood of the model;  $k$  is the model degrees of freedom calculated as the rank of variance-covariance matrix of the parameters  $e(V)$ , unless the `df()` option is specified; and  $N$  is the number of observations used in estimation or, more precisely, the number of independent terms in the likelihood. Operationally,  $N$  is defined as `e(N)`, unless the estimation command returns `e(N_ic)` or the `n()` option is specified with `estimates stats` or `estat ic`.

## Description

`icc` estimates intraclass correlations for one-way random-effects models, two-way random-effects models, or two-way mixed-effects models for both individual and average measurements. Intraclass correlations measuring consistency of agreement or absolute agreement of the measurements may be estimated.

## Quick start

Individual and average absolute-agreement intraclass correlation coefficients (ICCs) for ratings `y` of targets identified by `tid` in a one-way random-effects model

```
icc y tid
```

Same as above, but test that the individual and average ICCs are equal to 0.5

```
icc y tid, testvalue(.5)
```

Absolute-agreement ICCs for targets identified by `tid` and raters identified by `rid` in a two-way random-effects model

```
icc y tid rid
```

Same as above, but estimate consistency-of-agreement ICCs

```
icc y tid rid, consistency
```

Consistency-of-agreement ICCs when estimating random effects for targets and fixed effects for raters in a mixed-effects model

```
icc y tid rid, mixed
```

Same as above, but estimate absolute-agreement ICCs

```
icc y tid rid, mixed absolute
```

Same as above, but report 90% confidence intervals and test that ICCs are equal to 0.3

```
icc y tid rid, mixed absolute level(90) testvalue(.3)
```

\* `mixed` is required.

`bootstrap`, `by`, `collect`, `jackknife`, and `statsby` are allowed; see [\[U\] 11.1.10 Prefix commands](#).

## Options for one-way RE model

### Main

`absolute` specifies that intraclass correlations measuring absolute agreement of the measurements be estimated. This is the default for random-effects models.

`testvalue(#)` tests whether intraclass correlations equal #. The default is `testvalue(0)`.

### Reporting

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [\[R\] level](#).

`format(%fmt)` specifies how the intraclass correlation estimates and confidence intervals are to be formatted. The default is `format(%9.0g)`.

## Options for two-way RE and ME models

### Main

`mixed` is required to calculate two-way mixed-effects models. `mixed` specifies that intraclass correlations for a mixed-effects model be estimated.

`absolute` specifies that intraclass correlations measuring absolute agreement of the measurements be estimated. This is the default for random-effects models. Only one of `absolute` or `consistency` may be specified.

`consistency` specifies that intraclass correlations measuring consistency of agreement of the measurements be estimated. This is the default for mixed-effects models. Only one of `absolute` or `consistency` may be specified.

`testvalue(#)` tests whether intraclass correlations equal #. The default is `testvalue(0)`.

## Reporting

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [\[R\] level](#).

`format(%fmt)` specifies how the intraclass correlation estimates and confidence intervals are to be formatted. The default is `format(%9.0g)`.

## Remarks and examples

Remarks are presented under the following headings:

*Introduction*  
*One-way random effects*  
*Two-way random effects*  
*Two-way mixed effects*  
*Adoption study*  
*Relationship between ICCs*  
*Tests against nonzero values*

## Introduction

In some disciplines, such as psychology and sociology, data are often measured with error that can seriously affect statistical interpretation of the results. Thus, it is important to assess the amount of measurement error by evaluating the consistency or reliability of measurements. The intraclass correlation coefficient (ICC) is often used to measure the consistency or homogeneity of measurements.

Several versions of ICCs are introduced in the literature depending on the experimental design and goals of the study (see, for example, [Shrout and Fleiss \[1979\]](#) and [McGraw and Wong \[1996a\]](#)). Following [Shrout and Fleiss \(1979\)](#), we describe various forms of ICCs in the context of a reliability study of ratings of different targets (or objects of measurements) by several raters.

Consider  $n$  targets (for example, students, patients, athletes) that are randomly sampled from a population of interest. Each target is rated independently by a set of  $k$  raters (for example, teachers, doctors, judges). One rating per target and rater is obtained. It is of interest to determine the extent of the agreement of the ratings.

As noted by [Shrout and Fleiss \(1979\)](#) and [McGraw and Wong \(1996a\)](#), you need to answer several questions to decide what version of ICC is appropriate to measure the agreement in your study:

1. Is a one-way or two-way analysis-of-variance model appropriate for your study?
2. Are differences between raters' mean ratings relevant to the reliability of interest?
3. Is the unit of analysis an individual rating or the mean rating over several raters?
4. Is the consistency of agreement or the absolute agreement of ratings of interest?

Three types of analysis-of-variance models are considered for the reliability study: one-way random effects, two-way random effects, and two-way mixed effects. Mixed models contain both fixed effects and random effects. In the one-way random-effects model, each target is rated by a different set of  $k$  independent raters, who are randomly drawn from the population of raters. The target is the only random effect in this model; the effects due to raters and possibly due to rater-and-target interaction cannot be separated from random error. In the two-way random-effects model, each target is rated by the same set of  $k$  independent raters, who are randomly drawn from the population of raters. The random effects in this model are target and rater and possibly their interaction, although in the absence of repeated measurements for each rater on each target, the effect of an interaction cannot be separated from random error. In the two-way mixed-effects model, each target is rated by the same set of  $k$  independent raters. Because they are the only raters of interest, rater is a fixed effect. The random effects are target and possibly target-and-rater interaction, but again the interaction effect cannot be separated from random error without repeated measurements for each rater and target. The definition of ICC depends on the chosen random-effects model; see *Methods and formulas* for details.

In summary, use a one-way model if there are no systematic differences in measurements due to raters and use a two-way model otherwise. If you want to generalize your results to a population of raters from which the observed raters are sampled, use a two-way random-effects model, treating raters as random. If you are interested only in the effects of the observed  $k$  raters, use a two-way mixed-effects model, treating raters as fixed. For example, suppose you compare judges' ratings of targets from different groups. If you use the combined data from  $k$  judges to compare the groups, the random-effects model is appropriate. If you compare groups separately for each judge and then pool the differences, the mixed-effects model is appropriate.

The definition of ICC also depends on the unit of analysis in a study—whether the agreement is measured between individual ratings (individual ICC) or between the averages of ratings over several raters (average ICC). The data on individual ratings are more common. The data on average ratings are typically used when individual ratings are deemed unreliable. The average ICC can also be used when teams of raters are used to rate a target. For example, the ratings of teams of physicians may be evaluated in this manner. When the unit of analysis is an average rating, you should remember that the interpretation of ICC pertains to average ratings and not individual ratings.

Finally, depending on whether consistency of agreement or absolute agreement is of interest, two types of ICC are used: consistency-of-agreement ICC (CA-ICC) and absolute-agreement ICC (AA-ICC). Under consistency of agreement, the scores are considered consistent if the scores from any two raters differ by the same constant value for all targets. This implies that raters give the same ranking to all targets. Under absolute agreement, the scores are considered in absolute agreement if the scores from all raters match exactly.

For example, suppose we observe three targets and two raters. The ratings are (2,4), (4,6), and (6,8), with rater 1 giving the scores (2,4,6) and rater 2 giving the scores (4,6,8), two points higher than rater 1. The CA-ICC between individual ratings is 1 because the scores from rater 1 and rater 2 differ by a constant value (two points) for all targets. That rater 1 gives lower scores than rater 2 is deemed irrelevant under the consistency measure of agreement. The raters have the same difference of opinion on every target, and the variation between raters that is caused by this difference is not relevant. On the other hand, the AA-ICC between individual ratings is  $8/12 = 0.67$ , where 8 is the estimated between-target variance and 12 is the estimated total variance of ratings.

Either CA-ICC or AA-ICC can serve as a useful measure of agreement depending on whether rater variability is relevant for determining the degree of agreement. As [McGraw and Wong \(1996a\)](#) point out, CA-ICC is useful when comparative judgments are made about objects of measurement. The CA-ICC represents correlation when the rater is fixed; the AA-ICC represents correlation when the rater is random.

See [Shrout and Fleiss \(1979\)](#) and [McGraw and Wong \(1996a\)](#) for more detailed guidelines about the choice of appropriate ICC.

[Shrout and Fleiss \(1979\)](#) and [McGraw and Wong \(1996a\)](#) describe 10 versions of ICCs based on the concepts above: individual and average AA-ICCs for a one-way model (consistency of agreement is not defined for this model); individual and average AA-ICCs and CA-ICCs for a two-way random-effects model; and individual and average AA-ICCs and CA-ICCs for a two-way mixed-effects model. Although each of these ICCs has its own definition and interpretation, the estimators for some are identical, leading to the same estimates of those ICCs; see [Relationship between ICCs](#) and [Methods and formulas](#) for details.

The `icc` command calculates ICCs for each of the three analysis-of-variance models. You can use option `absolute` to compute AA-ICCs or option `consistency` to compute CA-ICCs. By default, `icc` computes ICCs corresponding to the correlation between ratings and between average ratings made on the same target: AA-ICC for a random-effects model and CA-ICC for a mixed-effects model. As pointed out by [Shrout and Fleiss \(1979\)](#), although the data on average ratings might be needed for reliability, the generalization of interest might be individuals. For this reason, `icc` reports ICCs for both units, individual and average, for each model.

In addition to estimates of ICCs, `icc` provides confidence intervals and one-sided  $F$  tests. The  $F$  test of  $H_0: \rho = 0$  versus  $H_a: \rho > 0$  is the same for the individual and average ICCs, so `icc` reports one test. This is not true, however, for nonzero null hypotheses (see [Tests against nonzero values](#) for details), so `icc` reports a separate test in this case.

The `icc` command requires data in long form; see [\[D\] reshape](#) for how to convert data in wide form to long form. The data must also be balanced and contain one observation per target and rater. For unbalanced data, `icc` omits all targets with fewer than  $k$  ratings from computation. Under one-way models,  $k$  is determined as the largest number of observed ratings for a target. Under two-way models,  $k$  is the number of unique raters. If multiple observations per target and rater are detected, `icc` issues an error.

We demonstrate the use of `icc` using datasets from [Shrout and Fleiss \(1979\)](#) and [McGraw and Wong \(1996a\)](#). In the next three sections, we use an example from table 2 of [Shrout and Fleiss \(1979\)](#) with six targets and four judges. For instructional purposes, we analyze these data under each of the three different models: one-way random effects, two-way random effects, and two-way mixed effects.

## One-way random effects

In the one-way random-effects model, we assume that the  $n$  targets being rated are randomly selected from the population of potential targets. Each is rated by a different set of  $k$  raters randomly drawn from the population of potential raters. McGraw and Wong (1996a) describe an example of this setting, where behavioral genetics data are used to assess familial resemblance. Family units can be viewed as “targets”, and children can be viewed as “raters”. By taking a measurement on a child of the family unit, we obtain the “rating” of the family unit by the “child-rater”. In this case, we can use ICC to assess similarity between children within a family or, in other words, assess if there is a family effect in these data.

As we mentioned in the introduction, only AA-ICC is defined for a one-way model. The consistency of agreement is not defined in this case, as each target is evaluated by a different set of raters. Thus, there is no between-rater variability in this model.

In a one-way model, the AA-ICC corresponds to the correlation coefficient between ratings within a target. It is also a ratio of the between-target variance of ratings to the total variance of ratings, the sum of the between-target and error variances.

### ▷ Example 1: One-way random-effects ICCs

Consider data from table 2 of Shrout and Fleiss (1979) stored in `judges.dta`. The data contain 24 ratings of  $n = 6$  targets by  $k = 4$  judges. We list the first eight observations:

```
. use https://www.stata-press.com/data/r19/judges
(Ratings of targets by judges)
. list in 1/8, sepby(target)
```

|    | rating | target | judge |
|----|--------|--------|-------|
| 1. | 9      | 1      | 1     |
| 2. | 2      | 1      | 2     |
| 3. | 5      | 1      | 3     |
| 4. | 8      | 1      | 4     |
| 5. | 6      | 2      | 1     |
| 6. | 1      | 2      | 2     |
| 7. | 3      | 2      | 3     |
| 8. | 2      | 2      | 4     |

For a moment, let’s ignore that targets are rated by the same set of judges. Instead, we assume that a different set of four judges is used to rate each target. In this case, the only systematic variation in the data is due to targets, so the one-way random-effects model is appropriate.

We use `icc` to estimate the intraclass correlations for these data. To compute ICCs for a one-way model, we specify the dependent variable `rating` followed by the target variable `target`:

```
. icc rating target
Intraclass correlations
One-way random-effects model
Absolute agreement
Random effects: target Number of targets = 6
 Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .1657418 | -.1329323            | .7225601 |
| Average    | .4427971 | -.8844422            | .9124154 |

```
F test that
ICC=0.00: F(5.0, 18.0) = 1.79 Prob > F = 0.165
```

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

`icc` reports the AA-ICCs for both individual and average ratings. The individual AA-ICC corresponds to  $ICC(1)$  in McGraw and Wong (1996a) or  $ICC(1,1)$  in Shrout and Fleiss (1979). The average AA-ICC corresponds to  $ICC(k)$  in McGraw and Wong (1996a) or  $ICC(1,k)$  in Shrout and Fleiss (1979).

The estimated correlation between individual ratings is 0.17, indicating little similarity between ratings within a target, low reliability of individual target ratings, or no target effect. The estimated intraclass correlation between ratings averaged over  $k = 4$  judges is higher, 0.44. (The average ICC will typically be higher than the individual ICC.) The estimated intraclass correlation measures the similarity or reliability of mean ratings from groups of four judges. We do not have statistical evidence that either ICC is different from zero based on reported confidence intervals and the one-sided  $F$  test.

Note that although the estimates of ICCs cannot be negative in this setting, the lower bound of the computed confidence interval may be negative. A common ad-hoc way of handling this is to truncate the lower bound at zero.

The estimates of both the individual and the average AA-ICC are also computed by the `lone` command (see [R] [lone](#)), which performs a one-way analysis of variance.

◀

## □ Technical note

Mean rating is commonly used when individual rating is unreliable because the reliability of a mean rating is always higher than the reliability of the individual rating when the individual reliability is positive.

In the [previous example](#), we estimated low reliability of the individual ratings of a target, 0.17. The reliability increased to 0.44 for the ratings averaged over four judges. What if we had more judges?

We can use the Spearman–Brown formula (Spearman 1910; Brown 1910) to compute the  $m$ -average ICC based on the individual ICC:

$$\text{ICC}(m) = \frac{m\text{ICC}(1)}{1 + (m - 1)\text{ICC}(1)}$$

Using this formula for the previous example, we find that the mean reliability over, say, 10 judges is  $10 \times 0.17 / (1 + 9 \times 0.17) = 0.67$ .

Alternatively, we can invert the Spearman–Brown formula to determine the number of judges (or the number of ratings of a target) we need to achieve the desired reliability. Suppose we would like an average reliability of 0.9, then

$$m = \frac{\text{ICC}(m)\{1 - \text{ICC}(1)\}}{\text{ICC}(1)\{1 - \text{ICC}(m)\}} = \frac{0.9(1 - 0.17)}{0.17(1 - 0.9)} = 44$$

See, for example, Bliese (2000) for other examples. □

## Two-way random effects

As before, we assume that the targets being rated are randomly selected from the population of potential targets. We now also assume that each target is evaluated by the same set of  $k$  raters, who have been randomly sampled from the population of raters. In this scenario, we want to generalize our findings to the population of raters from which the observed  $k$  raters were sampled. For example, suppose we want to estimate the reliability of doctors' evaluations of patients with a certain condition. Unless the reliability at a specific hospital is of interest, the doctors may be interchanged with others in the relevant population of doctors.

As for a one-way model, the AA-ICC corresponds to the correlation between measurements on the same target and is also a ratio of the between-target variance to the total variance of measurements in a two-way random-effects model. The total variance is now the sum of the between-target, between-rater, and error variances. Unlike a one-way model, the CA-ICC can be computed for a two-way random-effects model when the consistency of agreement is of interest rather than the absolute agreement. The CA-ICC is also the ratio of the between-target variance to the total variance, but the total variance does not include the between-rater variance because the between-rater variability is irrelevant for the consistency of agreement.

Again, the two versions, individual and average, are available for each ICC.

### ▷ Example 2: Two-way random-effects ICCs

Continuing with [example 1](#), recall that we previously ignored that each target is rated by the same set of four judges and instead assumed different sets of judges. We return to the original data setting. We want to evaluate the agreement between judges' ratings of targets in a population represented by the observed set of four judges.

In a two-way model, we must specify both the target and the rater variables. In `icc`, we now additionally specify the rater variable `judge` following the target variable `target`; the random-effects model is assumed by default.

```
. icc rating target judge
Intraclass correlations
Two-way random-effects model
Absolute agreement
Random effects: target Number of targets = 6
Random effects: judge Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .2897638 | .0187865             | .7610844 |
| Average    | .6200505 | .0711368             | .927232  |

```
F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000
```

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

As for a one-way random-effects model, `icc` by default reports AA-ICCs that correspond to the correlation between ratings on a target. Notice that both individual and average ICCs are larger in the two-way random-effects model than in the previous one-way model—0.29 versus 0.17 and 0.62 versus 0.44, respectively. We also have statistical evidence to reject the null hypothesis that neither ICC is zero based on confidence intervals and the  $F$  test. If a one-way model is used when a two-way model is appropriate, the true ICC will generally be underestimated.

The individual AA-ICC corresponds to  $ICC(A,1)$  in [McGraw and Wong \(1996a\)](#) or  $ICC(2,1)$  in [Shrout and Fleiss \(1979\)](#). The average AA-ICC corresponds to  $ICC(A,k)$  in [McGraw and Wong \(1996a\)](#) or  $ICC(2,k)$  in [Shrout and Fleiss \(1979\)](#).

Instead of the absolute agreement, we can also assess the consistency of agreement. The individual and average CA-ICCs are considered in [McGraw and Wong \(1996a\)](#) and denoted as  $ICC(C,1)$  and  $ICC(C,k)$ , respectively. These ICCs are not considered in [Shrout and Fleiss \(1979\)](#) because they are not correlations in the strict sense. Although CA-ICCs do not estimate correlation, they can provide useful information about the reliability of the raters. [McGraw and Wong \(1996a\)](#) note that the practical value of the individual and average CA-ICCs in the two-way random-effects model setting is well documented in measurement theory, citing [Hartmann \(1982\)](#) and [Suen \(1988\)](#).

To estimate the individual and average CA-ICCs, we specify the consistency option:

```
. icc rating target judge, consistency
Intraclass correlations
Two-way random-effects model
Consistency of agreement
Random effects: target Number of targets = 6
Random effects: judge Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .7148407 | .3424648             | .9458583 |
| Average    | .9093155 | .6756747             | .9858917 |

```
F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000
```

We estimate that the consistency of agreement of ratings in the considered population of raters is high, 0.71, based on the individual CA-ICC. On the other hand, the absolute agreement of ratings is low, 0.29, based on the individual AA-ICC from the previous output.

◀

The measure of consistency of agreement among means, the average CA-ICC, is equivalent to Cronbach's alpha (Cronbach 1951); see [MV] **alpha**. The individual CA-ICC can also be equivalent to the Pearson's correlation coefficient between raters when  $k = 2$ ; see McGraw and Wong (1996a) for details.

In the next example, we will see that the actual estimates of the individual and average AA-ICCs and CA-ICCs are the same whether we examine a random-effects model or a mixed-effects model. The differences between these ICCs are in their definitions and interpretations.

## Two-way mixed effects

As in a two-way random-effects model, we assume that the targets are randomly selected from the population of potential targets and that each is evaluated by the same set of  $k$  raters. In a mixed-effects model, however, we assume that these raters are the only raters of interest. So as before, the targets are random, but now the raters are fixed.

In the two-way mixed-effects model, the fixed effect of the rater does not contribute to the between-rater random variance component to the total variance. As such, the definitions and interpretations of ICCs are different in a mixed-effects model than in a random-effects model. However, the estimates of ICCs as well as test statistics and confidence intervals are the same. The only exceptions are average AA-ICCs and CA-ICCs. These are not estimable in a two-way mixed-effects model including an interaction term between target and rater; see *Relationship between ICCs* and *Methods and formulas* for details.

In a two-way mixed-effects model, the CA-ICC corresponds to the correlation between measurements on the same target. As pointed out by Shrout and Fleiss (1979), when the rater variance is ignored, the correlation coefficient is interpreted in terms of rater consistency rather than rater absolute agreement. Formally, the CA-ICC is the ratio of the covariance between measurements on the target to the total variance of the measurements. The AA-ICC corresponds to the same ratio, but includes a variance of the fixed factor, rater, in its denominator.

### ▶ Example 3: Two-way mixed-effects ICCs

Continuing with [example 2](#), suppose that we are now interested in assessing the agreement of ratings from only the observed four judges. The judges are now fixed effects, and the appropriate model is a two-way mixed-effects model.

To estimate ICCs for a two-way mixed-effects model, we specify the mixed option with `icc`:

```
. icc rating target judge, mixed
Intraclass correlations
Two-way mixed-effects model
Consistency of agreement
Random effects: target Number of targets = 6
Fixed effects: judge Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .7148407 | .3424648             | .9458583 |
| Average    | .9093155 | .6756747             | .9858917 |

```
F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000
```

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

As we described in the introduction, `icc` by default reports ICCs corresponding to the correlations. So, for a mixed-effects model, `icc` reports CA-ICCs by default. The individual and average CA-ICCs are denoted as  $ICC(3,1)$  and  $ICC(3,k)$  in [Shrout and Fleiss \(1979\)](#) and  $ICC(C,1)$  and  $ICC(C,k)$  in [McGraw and Wong \(1996a\)](#).

Our estimates of the individual and average CA-ICCs are identical to the CA-ICC estimates obtained under the two-way random-effects model in [example 2](#), but our interpretation of the results is different. Under a mixed-effects model, 0.71 and 0.91 are the estimates, respectively, of the correlation between individual measurements and the correlation between average measurements made on the same target.

We can also estimate the AA-ICCs in this setting by specifying the `absolute` option:

```
. icc rating target judge, mixed absolute
Intraclass correlations
Two-way mixed-effects model
Absolute agreement
Random effects: target Number of targets = 6
Fixed effects: judge Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .2897638 | .0187865             | .7610844 |
| Average    | .6200505 | .0711368             | .927232  |

```
F test that
ICC=0.00: F(5.0, 15.0) = 11.03 Prob > F = 0.000
```

The intraclass correlation estimates match the individual and average AA-ICCs obtained under the two-way random-effects model in [example 2](#); but in a mixed-effects model, they do not represent correlations. We demonstrate the use of an individual AA-ICC in a mixed-effects setting in the next example.

The AA-ICCs under a mixed-effects model are not considered by [Shrout and Fleiss \(1979\)](#). They are denoted as  $ICC(A,1)$  and  $ICC(A,k)$  in [McGraw and Wong \(1996a\)](#).

## Adoption study

In this section, we consider the adoption study described in [McGraw and Wong \(1996a\)](#). Adoption studies commonly include two effects of interest. One is the mean difference between the adopted child and its biological parents. It is used to determine if characteristics of adopted children differ on average from those of their biological parents. Another effect of interest is the correlation between genetically paired individuals and genetically unrelated individuals who live together. This effect is used to evaluate the impact of genetic differences on individual differences.

As discussed in [McGraw and Wong \(1996a\)](#), a consistent finding from adoption research using IQ as a trait characteristic is that while adopted children typically have higher IQs than their biological parents, their IQs correlate better with those of their biological parents than with those of their adoptive parents. Both effects are important, and there is additional need to reconcile the two findings. [McGraw and Wong \(1996a\)](#) propose to use the individual AA-ICC for this purpose.

### ► Example 4: Absolute-agreement ICC in a mixed-effects model

The `adoption.dta` dataset contains the data from table 6 of [McGraw and Wong \(1996a\)](#) on IQ scores:

```
. use https://www.stata-press.com/data/r19/adoption
(Biological mother and adopted child IQ scores)

. describe
Contains data from https://www.stata-press.com/data/r19/adoption.dta
Observations: 20 Biological mother and adopted
 child IQ scores
Variables: 5 15 May 2024 13:50
 (_dta has notes)
```

| Variable name | Storage type | Display format | Value label | Variable label                                  |
|---------------|--------------|----------------|-------------|-------------------------------------------------|
| family        | byte         | %9.0g          |             | Adoptive family ID                              |
| mc            | byte         | %9.0g          | mcvalues    | Whether mother or child                         |
| iq3           | int          | %9.0g          |             | IQ scores, mother-child<br>difference of 3 pts  |
| iq9           | int          | %9.0g          |             | IQ scores, mother-child<br>difference of 9 pts  |
| iq15          | int          | %9.0g          |             | IQ scores, mother-child<br>difference of 15 pts |

Sorted by:

The family variable contains adoptive family identifiers, the mc variable records a mother or a child, and the iq3, iq9, and iq15 variables record IQ scores with differences between mother and child mean IQ scores of 3, 9, and 15 points, respectively.

```
. by mc, sort: summarize iq*
```

```
-> mc = Mother
```

| Variable | Obs | Mean | Std. dev. | Min | Max |
|----------|-----|------|-----------|-----|-----|
| iq3      | 10  | 97   | 15.0037   | 62  | 116 |
| iq9      | 10  | 91   | 15.0037   | 56  | 110 |
| iq15     | 10  | 85   | 15.0037   | 50  | 104 |

```
-> mc = Child
```

| Variable | Obs | Mean | Std. dev. | Min | Max |
|----------|-----|------|-----------|-----|-----|
| iq3      | 10  | 100  | 15.0037   | 65  | 119 |
| iq9      | 10  | 100  | 15.0037   | 65  | 119 |
| iq15     | 10  | 100  | 15.0037   | 65  | 119 |

The variances of the mother and child IQ scores are the same.

Children are fixed effects, so the mixed-effects model is appropriate for these data. We want to compare individual CA-ICC with individual AA-ICC for each of the three IQ variables. We could issue a separate `icc` command for each of the three IQ variables to obtain the intraclass correlations. Instead, we use `reshape` to convert our data to long form with one `iq` variable and the new `diff` variable recording mean differences:

```
. reshape long iq, i(family mc) j(diff)
(j = 3 9 15)
```

| Data                   | Wide         | -> | Long |
|------------------------|--------------|----|------|
| Number of observations | 20           | -> | 60   |
| Number of variables    | 5            | -> | 4    |
| j variable (3 values)  |              | -> | diff |
| xij variables:         | iq3 iq9 iq15 | -> | iq   |

We can now use the `by` prefix with `icc` to estimate intraclass correlations for the three groups of interest:

```
. by diff, sort: icc iq family mc, mixed
```

```
-> diff = 3
```

```
Intraclass correlations
Two-way mixed-effects model
Consistency of agreement
```

```
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2
```

|            | iq | ICC      | [95% conf. interval] |          |
|------------|----|----------|----------------------|----------|
| Individual |    | .7142152 | .1967504             | .920474  |
| Average    |    | .8332853 | .3288078             | .9585904 |

```
F test that
```

```
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
```

```
Note: ICCs estimate correlations between individual measurements
and between average measurements made on the same target.
```

```
-> diff = 9
```

```
Intraclass correlations
Two-way mixed-effects model
Consistency of agreement
```

```
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2
```

|            | iq | ICC      | [95% conf. interval] |          |
|------------|----|----------|----------------------|----------|
| Individual |    | .7142152 | .1967504             | .920474  |
| Average    |    | .8332853 | .3288078             | .9585904 |

```
F test that
```

```
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
```

```
Note: ICCs estimate correlations between individual measurements
and between average measurements made on the same target.
```

```
-> diff = 15
```

```
(output omitted)
```

The estimated CA-ICCs are the same in all three groups and are equal to the corresponding estimates of the Pearson's correlation coefficients because mothers' and childrens' IQ scores have the same variability. The scores differ only in means, and mean differences are irrelevant when measuring the consistency of agreement.

The AA-ICCs, however, differ across the three groups:

```
. by diff, sort: icc iq family mc, mixed absolute
```

```
-> diff = 3
```

```
Intraclass correlations
Two-way mixed-effects model
Absolute agreement
```

```
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2
```

|            | iq | ICC      | [95% conf. interval] |          |
|------------|----|----------|----------------------|----------|
| Individual |    | .7204023 | .2275148             | .9217029 |
| Average    |    | .8374812 | .3706917             | .9592564 |

```
F test that
```

```
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
```

```
-> diff = 9
```

```
Intraclass correlations
Two-way mixed-effects model
Absolute agreement
```

```
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2
```

|            | iq | ICC      | [95% conf. interval] |          |
|------------|----|----------|----------------------|----------|
| Individual |    | .6203378 | .0293932             | .8905025 |
| Average    |    | .7656895 | .0571077             | .9420802 |

```
F test that
```

```
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
```

```
-> diff = 15
```

```
Intraclass correlations
Two-way mixed-effects model
Absolute agreement
```

```
Random effects: family Number of targets = 10
Fixed effects: mc Number of raters = 2
```

|            | iq | ICC      | [95% conf. interval] |          |
|------------|----|----------|----------------------|----------|
| Individual |    | .4854727 | -.1194157            | .8466905 |
| Average    |    | .6536272 | -.2712191            | .9169815 |

```
F test that
```

```
ICC=0.00: F(9.0, 9.0) = 6.00 Prob > F = 0.007
```

As the mean differences increase, the AA-ICCs decrease. Their attenuation reflects the difference in means between biological mother and child IQs while still measuring their agreement. Notice that for small mean differences, the estimates of AA-ICCs and CA-ICCs are very similar.

Note that our estimates match those given in [McGraw and Wong \(1996b\)](#), who correct the original table 6 of [McGraw and Wong \(1996a\)](#).

## Relationship between ICCs

In examples 2 and 3, we saw that the estimates of AA-ICCs and CA-ICCs are the same for two-way random-effects and two-way mixed-effects models. In this section, we consider the relationship between various forms of ICCs in more detail; also see *Methods and formulas*.

There are 10 different versions of ICCs, but only 6 different estimators are needed to compute them. These estimators include the two estimators for the individual and average AA-ICCs in a one-way model, the two estimators for the individual and average AA-ICCs in two-way models, and the two estimators for the individual and average CA-ICCs in two-way models.

Only individual and average AA-ICCs are defined for the one-way model. The estimates of AA-ICCs based on the one-way model will typically be smaller than individual and average estimates of AA-ICCs and CA-ICCs based on two-way models. The estimates of individual and average CA-ICCs will typically be larger than the estimates of individual and average AA-ICCs.

Although AA-ICCs and CA-ICCs have the same respective estimators in two-way random-effects and mixed-effects models, their definitions and interpretations are different. The AA-ICCs based on a random-effects model contain the between-rater variance component in the denominator of the variance ratio. The AA-ICCs based on a mixed-effects model contain the variance of the fixed-factor rater instead of the random between-rater variability. The AA-ICCs in a random-effects model represent correlations between any two measurements made on a target. The AA-ICCs in a mixed-effects model measure absolute agreement of measurements treating raters as fixed. The CA-ICCs for random-effects and mixed-effects models have the same definition but different interpretations. The CA-ICCs represent correlations between any two measurements made on a target in a mixed-effects model but estimate the degree of consistency among measurements treating raters as random in a random-effects model. The difference in the definitions of AA-ICCs and CA-ICCs is that CA-ICCs do not contain the between-rater variance in the denominator of the variance ratio.

For two-way models, the definitions and interpretations (but not the estimators) of ICCs also depend on whether the model contains an interaction between target and rater. For two-way models with interaction, ICCs include an additional variance component for the target-rater interaction in the denominator of the variance ratio. This component cannot be separated from random error because there is only one observation per target and rater.

Also, under a two-way mixed-effects model including interaction, the interaction components are not mutually independent, as they are in a two-way random-effects model. The considered version of the mixed-effects model places a constraint on the interaction effects—the sum of the interaction effects over levels of the fixed factor is zero; see, for example, chapter 7 in Kuehl (2000) for an introductory discussion of mixed models. In this version of the model, there is a correlation between the interaction effects. Specifically, the two interaction effects for the same target and two different raters are negatively correlated. As a result, the estimated intraclass correlation can be negative under a two-way mixed-effects model with interaction. Also, average AA-ICC and average CA-ICC cannot be estimated in a two-way mixed-effects model including interaction; see *Methods and formulas* and McGraw and Wong (1996a) for details.

## Tests against nonzero values

It may be of interest to test whether the intraclass correlation is equal to a value other than zero. `icc` supports testing against positive values through the use of the `testvalue()` option. Specifying `testvalue(#)` provides a one-sided hypothesis test of  $H_o: \rho = \#$  versus  $H_a: \rho > \#$ . The test is provided separately for both individual and average ICCs.

## ▷ Example 5: Testing ICC against a nonzero value

We return to the two-way random-effects model for the judge and target data from [Shrout and Fleiss \(1979\)](#). Suppose we want to test whether the individual and average AA-ICCs are each equal to 0.2. We specify the `testvalue(0.2)` option with `icc`:

```
. use https://www.stata-press.com/data/r19/judges, clear
(Ratings of targets by judges)
. icc rating target judge, testvalue(0.2)

Intraclass correlations
Two-way random-effects model
Absolute agreement

Random effects: target Number of targets = 6
Random effects: judge Number of raters = 4
```

| rating     | ICC      | [95% conf. interval] |          |
|------------|----------|----------------------|----------|
| Individual | .2897638 | .0187865             | .7610844 |
| Average    | .6200505 | .0711368             | .927232  |

```
F test that
ICC(1)=0.20: F(5.0, 5.3) = 1.54 Prob > F = 0.317
ICC(k)=0.20: F(5.0, 9.4) = 4.35 Prob > F = 0.026
```

Note: ICCs estimate correlations between individual measurements and between average measurements made on the same target.

We reject the null hypothesis that the average AA-ICC, labeled as  $ICC(k)$  in the output, is equal to 0.2, but we do not have statistical evidence to reject the null hypothesis that the individual AA-ICC, labeled as  $ICC(1)$ , is equal to 0.2.

## Methods and formulas

We observe  $y_{ij}$ , where  $i = 1, \dots, n$  and  $j = 1, \dots, k$ .  $y_{ij}$  is the  $j$ th rating on the  $i$ th target. Let  $\alpha = 1 - l/100$ , where  $l$  is the significance level specified by the user.

Methods and formulas are presented under the following headings:

*Mean squares*  
*One-way random effects*  
*Two-way random effects*  
*Two-way mixed effects*

## Mean squares

The mean squares within targets are

$$\text{WMS} = \sum_i \sum_j \frac{(y_{ij} - \bar{y}_{i.})^2}{n(k-1)}$$

where  $\bar{y}_{i.} = \sum_j y_{ij}/k$ .

The mean squares between targets are

$$\text{BMS} = \sum_i \frac{(\bar{y}_{i.} - \bar{y}_{..})^2}{n-1}$$

where  $\bar{y}_{..} = \sum_i \bar{y}_{i.}/n$ .

These are the only mean squares needed to estimate ICC in the one-way random-effects model. For the two-way models, we need two additional mean squares.

The mean squares between raters are

$$\text{JMS} = \sum_j \frac{(\bar{y}_{.j} - \bar{y}_{..})^2}{k-1}$$

where  $\bar{y}_{.j} = \sum_i y_{ij}/n$  and  $\bar{y}_{..} = \sum_j \bar{y}_{.j}/k$ .

The residual or error mean square is

$$\text{EMS} = \frac{\sum_i \sum_j (y_{ij} - \bar{y})^2 - (k-1)\text{JMS} - (n-1)\text{BMS}}{(n-1)(k-1)}$$

## One-way random effects

Under the one-way random-effects model, we observe

$$y_{ij} = \mu + r_i + \epsilon_{ij} \quad (\text{M1})$$

where  $\mu$  is the mean rating,  $r_i$  is the target random effect, and  $\epsilon_{ij}$  is random error. The  $r_i$ s are i.i.d.  $N(0, \sigma_r^2)$ ;  $\epsilon_{ij}$ s are i.i.d.  $N(0, \sigma_\epsilon^2)$  and are independent of  $r_i$ s. There is no rater effect separate from the residual error because each target is evaluated by a different set of raters.

The individual AA-ICC is the correlation between individual measurements on the same target:

$$\rho_1 = \text{ICC}(1) = \text{Corr}(y_{ij}, y_{ij'}) = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_\epsilon^2}$$

The average AA-ICC is the correlation between average measurements of size  $k$  made on the same target:

$$\rho_k = \text{ICC}(k) = \text{Corr}(\bar{y}_i, \bar{y}'_i) = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_\epsilon^2/k}$$

They are estimated by

$$\hat{\rho}_1 = \widehat{\text{ICC}}(1) = \frac{\text{BMS} - \text{WMS}}{\text{BMS} + (k-1)\text{WMS}}$$

$$\hat{\rho}_k = \widehat{\text{ICC}}(k) = \frac{\text{BMS} - \text{WMS}}{\text{BMS}}$$

**Confidence intervals.** Let  $F_{\text{obs}} = \text{BMS}/\text{WMS}$ , let  $F_l$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{n-1, n(k-1)}$  distribution, and let  $F_u$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{n(k-1), n-1}$  distribution. Let  $F_L = F_{\text{obs}}/F_l$  and  $F_U = F_{\text{obs}}F_u$ .

A  $(1 - \alpha) \times 100\%$  confidence interval for  $\rho_1$  is

$$\left( \frac{F_L - 1}{F_l + k - 1}, \frac{F_U - 1}{F_U + k - 1} \right) \quad (1)$$

A  $(1 - \alpha) \times 100\%$  confidence interval for  $\rho_k$  is

$$\left( 1 - \frac{1}{F_L}, 1 - \frac{1}{F_U} \right) \quad (2)$$

**Hypothesis tests.** Consider a one-sided hypothesis test of  $H_0: \text{ICC} = \rho_0$  versus  $H_a: \text{ICC} > \rho_0$ .

The test statistic for  $\rho_1$  is

$$F_{\rho_1} = \frac{\text{BMS}}{\text{WMS}} \frac{1 - \rho_0}{1 + (k-1)\rho_0} \quad (3)$$

The test statistic for  $\rho_k$  is

$$F_{\rho_k} = \frac{\text{BMS}}{\text{WMS}} (1 - \rho_0) \quad (4)$$

Under the null hypothesis, both  $F_{\rho_1}$  and  $F_{\rho_k}$  have the  $F_{n-1, n(k-1)}$  distribution. When  $\rho_0 = 0$ , the two test statistics coincide.

## Two-way random effects

In this setting, the target is evaluated by the same set of raters, who are randomly drawn from the population of raters. The underlying models with and without interaction are

$$y_{ij} = \mu + r_i + c_j + (rc)_{ij} + \epsilon_{ij} \quad (\text{M2})$$

$$y_{ij} = \mu + r_i + c_j + \epsilon_{ij} \quad (\text{M2A})$$

where  $y_{ij}$  is the rating of the  $i$ th target by the  $j$ th rater,  $\mu$  is the mean rating,  $r_i$  is the target random effect,  $c_j$  is the rater random effect,  $(rc)_{ij}$  is the target-rater random effect, and  $\epsilon_{ij}$  is random error. The  $r_i$ s are i.i.d.  $N(0, \sigma_r^2)$ ,  $c_j$ s are i.i.d.  $N(0, \sigma_c^2)$ ,  $(rc)_{ij}$ s are i.i.d.  $N(0, \sigma_{rc}^2)$ , and  $\epsilon_{ij}$ s are i.i.d.  $N(0, \sigma_\epsilon^2)$ . Each effect is mutually independent of the others.

Below, we provide formulas for ICCs for model (M2). The corresponding ICCs for model (M2A) can be obtained by setting  $\sigma_{rc}^2 = 0$ .

The individual AA-ICC is the correlation between individual measurements on the same target:

$$\rho_{A,1} = \text{ICC}(A,1) = \text{Corr}(y_{ij}, y_{ij'}) = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_c^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}$$

The average AA-ICC is the correlation between average measurements of size  $k$  made on the same target:

$$\rho_{A,k} = \text{ICC}(A,k) = \text{Corr}(\bar{y}_{i\cdot}, \bar{y}'_{i\cdot}) = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_c^2 + \sigma_{rc}^2 + \sigma_\epsilon^2)/k}$$

The consistency-of-agreement intraclass correlation for individual measurements, individual CA-ICC, is

$$\rho_{C,1} = \text{ICC}(C,1) = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}$$

The consistency-of-agreement intraclass correlation for average measurements of size  $k$ , average CA-ICC, is

$$\rho_{C,k} = \text{ICC}(C,k) = \frac{\sigma_r^2}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)/k}$$

With one observation per target and rater,  $\sigma_{rc}^2$  and  $\sigma_\epsilon^2$  cannot be estimated separately.

The estimators of intraclass correlations, confidence intervals, and test statistics are the same for models (M2) and (M2A). The estimators of ICCs are

$$\begin{aligned} \hat{\rho}_{A,1} &= \widehat{\text{ICC}}(A,1) = \frac{\text{BMS} - \text{EMS}}{\text{BMS} + (k-1)\text{EMS} + \frac{k}{n}(\text{JMS} - \text{EMS})} \\ \hat{\rho}_{A,k} &= \widehat{\text{ICC}}(A,k) = \frac{\text{BMS} - \text{EMS}}{\text{BMS} + \frac{1}{n}(\text{JMS} - \text{EMS})} \\ \hat{\rho}_{C,1} &= \widehat{\text{ICC}}(C,1) = \frac{\text{BMS} - \text{EMS}}{\text{BMS} + (k-1)\text{EMS}} \\ \hat{\rho}_{C,k} &= \widehat{\text{ICC}}(C,k) = \frac{\text{BMS} - \text{EMS}}{\text{BMS}} \end{aligned}$$

**Confidence intervals.** Let  $a = k\hat{\rho}_{A,1}/\{n(1 - \hat{\rho}_{A,1})\}$ ,  $b = 1 + k\hat{\rho}_{A,1}(n - 1)/\{n(1 - \hat{\rho}_{A,1})\}$ , and

$$v = \frac{(a\text{JMS} + b\text{EMS})^2}{\frac{a^2\text{JMS}^2}{k-1} + \frac{b^2\text{EMS}^2}{(n-1)(k-1)}} \tag{5}$$

Let  $F_l$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{n-1,v}$  distribution and  $F_u$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{v,n-1}$  distribution.

A  $(1 - \alpha) \times 100\%$  confidence interval for  $\rho_{A,1}$  is given by  $(L, U)$ , where

$$L = \frac{n(\text{BMS} - F_l\text{EMS})}{F_l\{k\text{JMS} + (kn - k - n)\text{EMS}\} + n\text{BMS}}$$

$$U = \frac{n(F_u\text{BMS} - \text{EMS})}{k\text{JMS} + (kn - k - n)\text{EMS} + nF_u\text{BMS}}$$
(6)

A  $(1 - \alpha) \times 100\%$  confidence intervals for  $\rho_{A,k}$  is a special case of (6) with  $k = 1$ , where  $a = \hat{\rho}_{A,k}/\{n(1 - \hat{\rho}_{A,k})\}$ ,  $b = 1 + \hat{\rho}_{A,k}(n - 1)/\{n(1 - \hat{\rho}_{A,k})\}$ , and  $v$  is defined in (5).

To define confidence intervals for  $\rho_{C,1}$  and  $\rho_{C,k}$ , let  $F_{\text{obs}} = \text{BMS}/\text{EMS}$ ,  $F_l$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{n-1,(n-1)(k-1)}$  distribution, and  $F_u$  be the  $(1 - \alpha/2) \times 100$ th percentile of the  $F_{(n-1)(k-1),n-1}$  distribution. Let  $F_L = F_{\text{obs}}/F_l$  and  $F_U = F_{\text{obs}}F_u$ .

A  $(1 - \alpha) \times 100\%$  confidence intervals for  $\rho_{C,1}$  and  $\rho_{C,k}$  are then as given by (1) and (2) for model (M1).

**Hypothesis tests.** Consider a one-sided hypothesis test of  $H_0: \text{ICC} = \rho_0$  versus  $H_a: \text{ICC} > \rho_0$ . Let  $a = k\rho_0/\{n(1 - \rho_0)\}$  and  $b = 1 + k\rho_0(n - 1)/\{n(1 - \rho_0)\}$ .

The test statistic for  $\rho_{A,1}$  is

$$F_{\rho_{A,1}} = \frac{\text{BMS}}{a\text{JMS} + b\text{EMS}}$$

Under the null hypothesis,  $F_{\rho_{A,1}}$  has the  $F_{n-1,v}$  distribution, where  $v$  is defined in (5).

The test statistic for  $\rho_{A,k}$  is defined similarly, except  $a = \rho_0/\{n(1 - \rho_0)\}$  and  $b = 1 + \rho_0(n - 1)/\{n(1 - \rho_0)\}$ . Under the null hypothesis,  $F_{\rho_{A,k}}$  has the  $F_{n-1,v}$  distribution, where  $v$  is defined in (5). When  $\rho_0 = 0$ , then  $a = 0$ ,  $b = 1$ , and the two test statistics coincide.

The test statistics for  $\rho_{C,1}$  and  $\rho_{C,k}$  are defined by (3) and (4), respectively, with WMS replaced by EMS. Under the null hypothesis, both  $F_{\rho_{C,1}}$  and  $F_{\rho_{C,k}}$  have the  $F_{n-1,(n-1)(k-1)}$  distribution. They also both have the same value when  $\rho_0 = 0$ .

## Two-way mixed effects

In this setting, every target is evaluated by the same set of judges, who are the only judges of interest. The underlying models with and without interaction are

$$y_{ij} = \mu + r_i + c_j + (rc)_{ij} + \epsilon_{ij} \tag{M3}$$

$$y_{ij} = \mu + r_i + c_j + \epsilon_{ij} \tag{M3A}$$

where  $y_{ij}$  is the rating of the  $i$ th target by the  $j$ th rater,  $\mu$  is the mean rating,  $r_i$  is the target random effect,  $c_j$  is the rater random effect,  $(rc)_{ij}$  is an interaction effect between target and rater, and  $\epsilon_{ij}$  is random error. The  $r_i$ s are i.i.d.  $N(0, \sigma_r^2)$ ,  $(rc)_{ij}$ s are  $N(0, \sigma_{rc}^2)$ , and  $\epsilon_{ij}$ s are i.i.d.  $N(0, \sigma_\epsilon^2)$ . Each random effect is mutually independent of the others. The  $c_j$ s are fixed such that  $\sum_j c_j = 0$ . The variance of  $c_j$ s is  $\theta_c^2 = \sum c_j^2 / (k - 1)$ .

In the presence of an interaction, two versions of a mixed-effects model may be considered. One assumes that  $(rc)_{ij}$ s are i.i.d.  $N(0, \sigma_{rc}^2)$ . Another assumes that  $(rc)_{ij}$ s are  $N(0, \sigma_{rc}^2)$  with an additional constraint that  $\sum_j (rc)_{ij} = 0$  (for example, [Kuehl \[2000\]](#)), so only interaction terms involving different targets are independent. The latter model is considered here.

We now define the intraclass correlations for individual measurements for model (M3).

The individual CA-ICC, the correlation between individual measurements on the same target, is

$$\rho_{C,1} = \text{ICC}(C,1) = \text{Corr}(y_{ij}, y_{ij'}) = \frac{\sigma_r^2 - \sigma_{rc}^2 / (k - 1)}{\sigma_r^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}$$

The absolute-agreement intraclass correlation for individual measurements, individual AA-ICC, is

$$\rho_{A,1} = \text{ICC}(A,1) = \frac{\sigma_r^2 - \sigma_{rc}^2 / (k - 1)}{\sigma_r^2 + \theta_c^2 + (\sigma_{rc}^2 + \sigma_\epsilon^2)}$$

[Shrout and Fleiss \(1979\)](#) show that the individual ICC could be negative in this case—a phenomenon first pointed out by [Sitgreaves \(1960\)](#). This can happen when the interaction term has a high variance relative to the targets and there are not many raters.

The individual intraclass correlations for model (M3A) have similar definitions with  $\sigma_{rc}^2 = 0$ . The individual CA-ICC is the correlation between individual measurements on the same target,  $\text{Corr}(y_{ij}, y_{ij'})$ .

We now discuss the intraclass correlations that correspond to average measurements. Neither average AA-ICC,  $\rho_{A,k}$ , nor average CA-ICC,  $\rho_{C,k}$ , can be estimated under model (M3) ([Shrout and Fleiss 1979](#); [McGraw and Wong 1996a](#)). The problem is that in this model,  $\sigma_r^2$ , which is the covariance between two means based on  $k$  raters, cannot be estimated.

Specifically, the parameter  $\sigma_r^2$  appears only in the expectation of the between-target mean squares BMS. Under the restriction  $\sum_j (rc)_{ij} = 0$ ,

$$E(\text{BMS}) = k\sigma_r^2 + \sigma_\epsilon^2$$

Note that  $\sigma_{rc}^2$  does not appear in the expectation of between-target mean squares. With one observation per target and rater,  $\sigma_r^2$  and  $\sigma_\epsilon^2$  cannot be estimated separately (only their sum  $\sigma_{rc}^2 + \sigma_\epsilon^2$  can be estimated), so BMS alone cannot be used to estimate  $\sigma_r^2$ .

Under model (M3A), however, there is no interaction (and thus no interaction variance component  $\sigma_{rc}^2$ ), so  $\rho_{A,k}$  or  $\rho_{C,k}$  can be estimated.

The average AA-ICC, the absolute-agreement intraclass correlation for average measurements of size  $k$ , is

$$\rho_{A,k} = \text{ICC}(A,k) = \frac{\sigma_r^2}{\sigma_r^2 + (\theta_c^2 + \sigma_\epsilon^2) / k}$$

The average CA-ICC, the correlation between average measurements of size  $k$  made on the same target, is

$$\rho_{C,k} = \text{ICC}(C,k) = \text{Corr}(\bar{y}_i, \bar{y}'_i) = \frac{\sigma_r^2}{\sigma_r^2 + \sigma_\epsilon^2 / k}$$

The estimators of ICCs, their confidence intervals, and hypothesis tests are as described for two-way random-effects models, except  $\rho_{A,k}$  and  $\rho_{C,k}$  are not defined under model (M3).

## Description

There are different approaches for measuring inequality and poverty, and different methods for summarizing the distribution of earnings, income, and wealth. Stata has some official features for these types of analyses. For example, the `roctab` command has an option to report Gini and Pietra indices, which are measures of income inequality; see [R] [roctab](#). With the `cumul` command, you can obtain the cumulative distribution function of, for example, household expenditures; see [R] [cumul](#). Additionally, you may want to look at the shape of income distributions; see [R] [kdensity](#) and [R] [histogram](#).

However, you might also be interested in the generalized Lorenz curve or a welfare index, which cannot be obtained from any official Stata commands. Fortunately, Stata users have developed an excellent suite of commands that create these graphs and report these types of indices, along with many other related measures. In this entry, we demonstrate how to find and install community-contributed commands related to inequality, poverty, and distributional summaries of earnings, income, and wealth.

## Remarks and examples

Suppose you are in search of a command to report inequality indices; you could type the following:

```
. search inequality
```

First, you will see official resources related to this keyword, including frequently asked questions (FAQs) and *Stata Journal* articles. Then, you will see community-contributed additions to Stata that are available from the internet, which typically include additions published in the *Stata Journal* and those posted on the Statistical Software Components (SSC) Archive, provided by <http://repec.org>. For example, in the output from `search`, we find `ineqdec0`, which calculates inequality indices with decomposition by subgroup.

### Search of web resources from Stata and other users

(output omitted)

```
ineqdec0 from http://fmwww.bc.edu/RePEc/bocode/i
'INEQDECO': module to calculate inequality indices with decomposition by
subgroup / ineqdec0 is a stripped-down version of ineqdeco (q.v.). /
Unlike the latter, it will provide estimates using samples /containing
zero or negative values for the variable of / interest. But as a result
ineqdecgini from http://fmwww.bc.edu/RePEc/bocode/i
'INEQDECGINI': module to estimate Gini coefficient with optional
decomposition by subgroups / ineqdecgini estimates the Gini coefficient
(a.k.a. Gini index) / of inequality plus, optionally, a decomposition by
population / subgroup into components representing inequality within /
```

(output omitted)

(end of search)

Let's take a closer look at this package:

1. Click on *ineqdec0* from <http://fmwww.bc.edu/RePEc/bocode/i>.
2. Click on *ineqdec0.hlp*.

This leads us to the help file, where we could learn more about which indices are computed with this package. This particular command supports *fweights* and *awweights*, but not all community-contributed commands do; it is important to look at the help file and confirm whether the command is a good fit for the analysis you want to perform. If it is, you can install it:

3. Click on the back button.
4. Click on *click here to install*.

Once you see a message indicating that the installation is complete, you may now use this command.

Another thing to keep in mind when installing packages is whether they are designed to work with complex survey data. This particular command is not. We can click on the back button once to return to the description of *ineqdec0* and then once more to return to the search results. Scrolling up, we come across

**Search of official help files, FAQs, Examples, and Stata Journals**

(output omitted)

```
SJ-16-2 st0427_1 Software update for conindex
. O. O'Donnell, S. O'Neill, T. Van Ourti, and B. Walsh
(help conindex if installed)
Q2/16 SJ 16(2):521--522
program can now be used on data from complex survey designs
```

(output omitted)

(end of search)

This is an update for a package called *conindex*; this updated version of the command can be used with data from complex survey designs. The original version of the package was introduced in *Stata Journal* Volume 16 Number 1 (March 2016), and this update was published the following quarter. If we scroll up a bit more in the search results, we will find an even more recent update:

**Search of official help files, FAQs, Examples, and Stata Journals**

(output omitted)

```
SJ-18-3 st0427_2 Software update for conindex
. O. O'Donnell, S. O'Neill, T. Van Ourti, and B. Walsh
(help conindex if installed)
Q3/18 SJ 18(3):758--759
uses the community-contributed lorenz command and fix a small bug
in the graph option
```

(output omitted)

(end of search)

It is best to install the most recent version, which we can do as follows:

1. Click on *st0427\_2*.
2. Click on *click here to install*.

The examples above demonstrate how to install community-contributed commands related to measures of inequality, but you would follow the same steps to find and install commands related to poverty measures, indices of social welfare, and the like.

For example, type the following:

```
. search poverty
```

In the list of results, you will find `g1curve`, which can be used to draw Lorenz curves, concentration curves, and other related curves. We can install this command as follows:

1. Click on `g1curve` from <http://fmwww.bc.edu/RePEc/bocode/g>.
2. Click on *click here to install*.

These are just a few examples of the many community-contributed commands that are available. You can use `search` to find more community-contributed commands used to obtain other measures of inequality and poverty, and distributional summaries of earnings, income, and wealth.

[Max Otto Lorenz](#) (1876–1959) was born in Burlington, Iowa. He did his undergraduate studies at the University of Iowa and received his PhD from the University of Wisconsin–Madison in 1906. In 1905, he published his only article, “Methods of measuring the concentration of wealth”, in a scientific journal. In the article, he introduces what we now call the Lorenz curve, a term first introduced in a statistics textbook in 1912.

Lorenz worked his whole life in governmental statistical institutions. He was the Deputy Commissioner of Labor and Industrial Statistics for Wisconsin, worked for the US Bureau of the Census and the Bureau of Railway Economics, and was the Director of the Bureau of Statistics and the Bureau of Transport and Economic Statistics.

His hobbies included calendar reform and Interlingua, a proposed international language.

[Description](#)[Remarks and examples](#)[Quick start](#)[Stored results](#)[Menu](#)[Methods and formulas](#)[Syntax](#)[References](#)[Options](#)[Also see](#)

## Description

`intreg` fits a linear model with an outcome measured as point data, interval data, left-censored data, or right-censored data. As such, it is a generalization of the model fit by `tobit`.

## Quick start

Regression on `x1` and `x2` of an interval-measured dependent variable with lower endpoint `y_lower` and upper endpoint `y_upper`

```
intreg y_lower y_upper x1 x2
```

With robust standard errors

```
intreg y_lower y_upper x1 x2, vce(robust)
```

Model heteroskedasticity in the conditional variance as a function of `x3`

```
intreg y_lower y_upper x1 x2, het(x3)
```

Adjust for complex survey design using `svyset` data

```
svy: intreg y_lower y_upper x1 x2
```

## Menu

Statistics > Linear models and related > Censored regression > Interval regression

## Syntax

```
intreg depvar1 depvar2 [indepvars] [if] [in] [weight] [, options]
```

*depvar*<sub>1</sub> and *depvar*<sub>2</sub> should have the following form:

| Type of data        |                | <i>depvar</i> <sub>1</sub> | <i>depvar</i> <sub>2</sub> |
|---------------------|----------------|----------------------------|----------------------------|
| point data          | $a = [a, a]$   | <i>a</i>                   | <i>a</i>                   |
| interval data       | $[a, b]$       | <i>a</i>                   | <i>b</i>                   |
| left-censored data  | $(-\infty, b]$ | .                          | <i>b</i>                   |
| right-censored data | $[a, +\infty)$ | <i>a</i>                   | .                          |
| missing             |                | .                          | .                          |

| <i>options</i>                                               | Description                                                                                                                                                                 |
|--------------------------------------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>Model</b>                                                 |                                                                                                                                                                             |
| <code>noconstant</code>                                      | suppress constant term                                                                                                                                                      |
| <code>het(<i>varlist</i> [, <code>noconstant</code>])</code> | independent variables to model the variance; use <code>noconstant</code> to suppress constant term                                                                          |
| <code>offset(<i>varname</i>)</code>                          | include <i>varname</i> in model with coefficient constrained to 1                                                                                                           |
| <code>constraints(<i>constraints</i>)</code>                 | apply specified linear constraints                                                                                                                                          |
| <b>SE/Robust</b>                                             |                                                                                                                                                                             |
| <code>vce(<i>vcetype</i>)</code>                             | <i>vcetype</i> may be <code>oim</code> , <code>robust</code> , <code>cluster <i>clustvar</i></code> , <code>opg</code> , <code>bootstrap</code> , or <code>jackknife</code> |
| <b>Reporting</b>                                             |                                                                                                                                                                             |
| <code>level(#)</code>                                        | set confidence level; default is <code>level(95)</code>                                                                                                                     |
| <code>nocnsreport</code>                                     | do not display constraints                                                                                                                                                  |
| <code>display_options</code>                                 | control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling                            |
| <b>Maximization</b>                                          |                                                                                                                                                                             |
| <code>maximize_options</code>                                | control the maximization process; seldom used                                                                                                                               |
| <code>collinear</code>                                       | keep collinear variables                                                                                                                                                    |
| <code>coeflegend</code>                                      | display legend instead of statistics                                                                                                                                        |

*indepvars* and *varlist* may contain factor variables; see [U] 11.4.3 Factor variables.

*depvar*<sub>1</sub>, *depvar*<sub>2</sub>, *indepvars*, and *varlist* may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fmm`, `fp`, `jackknife`, `mfp`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] `bayes: intreg` and [FMM] `fmm: intreg`.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`aweight`s are not allowed with the `jackknife` prefix; see [R] `jackknife`.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] `svy`.

`aweight`s, `fweight`s, `ilweight`s, and `pweight`s are allowed; see [U] 11.1.6 `weight`.

`collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`noconstant`; see [R] [Estimation options](#).

`het` (*varlist* [ , `noconstant`]) specifies that the logarithm of the standard deviation be modeled as a linear combination of *varlist*. The constant is included unless `noconstant` is specified.

`offset` (*varname*), `constraints` (*constraints*); see [R] [Estimation options](#).

### SE/Robust

`vce` (*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level` (#), `nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap` (#), `fvwrapon` (*style*), `cformat` (*%fmt*), `pformat` (*%fmt*), `sformat` (*%fmt*), and `nolstretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique` (*algorithm\_spec*), `iterate` (#), `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance` (#), `ltolerance` (#), `nrtolerance` (#), `nonrtolerance`, and `from` (*init\_specs*); see [R] [Maximize](#). These options are seldom used.

Setting the optimization type to `technique` (`bhhh`) resets the default *vcetype* to `vce` (`opg`).

The following options are available with `intreg` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

`intreg` fits a linear model to an outcome that may be either observed exactly or unobserved but known to fall within some interval. The values of the outcome variable may be observed (point data), unobserved but known to fall within an interval with fixed endpoints (interval-censored data), unobserved but known to fall within an interval that has a fixed upper endpoint (left-censored data), or unobserved but known to fall within an interval that has a fixed lower endpoint (right-censored data). Such censored data arise naturally in many contexts, such as wage data. Often, you know only that, for example, a person's salary is between \$30,000 and \$40,000.

The interval regression model fit by `intreg` is a generalization of the models fit by `tobit` because it extends censoring beyond left-censored data or right-censored data; see [Cameron and Trivedi \(2022, 965–967\)](#) for additional discussion of these data types. See [Wooldridge \(2020, sec. 17.4\)](#) for an introduction to censored and truncated regression models.

Regardless of the type of censoring, `intreg` requires the outcome to be stored in the dataset as interval data. That is, two dependent variables, `depvar1` and `depvar2`, are used to hold the endpoints of the interval. If the data are left-censored, the lower endpoint is  $-\infty$  and is represented by a missing value in `depvar1`. If the data are right-censored, the upper endpoint is  $+\infty$  and is represented by a missing value in `depvar2`. Point data are represented by the two endpoints being equal. Truly missing values of the dependent variable must be represented by missing values in both `depvar1` and `depvar2`.

### ▷ Example 1: Interval regression

`womenwage2.dta` contains the yearly wages of working women in interval form. Women were asked to indicate a category for their yearly income from employment. The categories were \$5,000 or less, \$5,001–\$10,000, ..., \$25,001–\$30,000, \$30,001–\$40,000, \$40,001–\$50,000, and more than \$50,000. The lower and upper endpoints of the wage categories (in \$1,000s) are recorded in variables `wage1` and `wage2`. Below, we list the first 10 observations in `wage1` and `wage2`.

```
. use https://www.stata-press.com/data/r19/womenwage2
(Wages of women, fictional data)
. list wage1 wage2 in 1/10
```

|     | wage1 | wage2 |
|-----|-------|-------|
| 1.  | .     | 5     |
| 2.  | 5     | 10    |
| 3.  | 5     | 10    |
| 4.  | 10    | 15    |
| 5.  | 15    | 20    |
| 6.  | 20    | 25    |
| 7.  | 25    | 30    |
| 8.  | 30    | 40    |
| 9.  | 40    | 50    |
| 10. | 50    | .     |

We see, for example, that the first respondent made \$5,000 or less in a year, that the second respondent made between \$5,001 and \$10,000 in a year, and so on. The tenth respondent made at least \$50,000 a year.

We now fit an interval regression model of women’s wages using social and demographic characteristics as explanatory variables. The variables include the subject’s age (age), years of schooling (school), job tenure (tenure), a dummy for living in a rural area (rural), and a dummy for never being married (nev\_mar).

```
. intreg wage1 wage2 age c.age#c.age i.nev_mar i.rural school tenure

Because the conditional mean modeled by interval regression is linear, the coefficients are interpreted the same way they are in ordinary least-squares regression; see [R] regress. For example, residing in a rural area lowers the expected income by \$3,043 and each additional year of schooling raises the expected income by \$1,335.

□ Technical note

Instead of using intervals to record wages, we could treat the outcome as categorical with a higher category corresponding to a higher wage. Here we fit an ordered probit model for wagecat, created based on groups defined by the intervals, by using `oprobit` (see [R] [oprobit](#)) with the same covariates:

```
. oprobit wagecat age c.age#c.age i.nev_mar i.rural school tenure
Iteration 0: Log likelihood = -881.1491
Iteration 1: Log likelihood = -764.31729
Iteration 2: Log likelihood = -763.31191
Iteration 3: Log likelihood = -763.31049
Iteration 4: Log likelihood = -763.31049
Ordered probit regression
Log likelihood = -763.31049
Number of obs = 488
LR chi2(6) = 235.68
Prob > chi2 = 0.0000
Pseudo R2 = 0.1337
```

| wagecat     | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |           |

| /cut6       | 6.922726    | .9215455  |       |       | 5.11653              | 8.728922  |
| /cut7       | 7.34471     | .9237628  |       |       | 5.534168             | 9.155252  |
| /cut8       | 7.963441    | .9338881  |       |       | 6.133054             | 9.793828  |

We can directly compare the log likelihoods for the `intreg` and `oprobit` models because both likelihoods are discrete. If we had point data in our `intreg` estimation, the likelihood would be a mixture of discrete and continuous terms, and we could not compare it directly with the `oprobit` likelihood.

Here the oprobit log likelihood is significantly larger (that is, less negative), so it fits better than the intreg model. The intreg model assumes normality, but the distribution of wages is skewed and definitely nonnormal. Normality is more closely approximated if we model the log of wages.

```
. generate logwage1 = log(wage1)
(14 missing values generated)
. generate logwage2 = log(wage2)
(6 missing values generated)
. intreg logwage1 logwage2 age c.age#c.age i.nev_mar i.rural school tenure

Fitting constant-only model:
Iteration 0: Log likelihood = -889.23647
Iteration 1: Log likelihood = -889.06346
Iteration 2: Log likelihood = -889.06346

Fitting full model:
Iteration 0: Log likelihood = -773.81968
Iteration 1: Log likelihood = -773.36566
Iteration 2: Log likelihood = -773.36563

Interval regression
 Number of obs = 488
 Uncensored = 0
 Left-censored = 14
 Right-censored = 6
 Interval-cens. = 468
 LR chi2(6) = 231.40
 Prob > chi2 = 0.0000

Log likelihood = -773.36563
```

|             | Coefficient | Std. err. | z      | P> z  | [95% conf. interval] |           |
|-------------|-------------|-----------|--------|-------|----------------------|-----------|

| <code>e(sample)</code>       | marks estimation sample                                                  |

In addition to the above, the following is stored in `r()`:

|                       |                                                                                                                       |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------|
| Matrices              |                                                                                                                       |
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

The regression equation of interest is

$$y_j = \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j$$

where  $y_j$  is a continuous outcome for the  $j$ th observation—either observed or unobserved—with covariates  $\mathbf{x}_j$  and corresponding coefficients  $\boldsymbol{\beta}$ . The model assumes that the error term is normally distributed;  $\epsilon \sim N(0, \sigma^2)$ .

For observations  $j \in \mathcal{C}$ , we observe  $y_j$ , that is, point data. Observations  $j \in \mathcal{I}$  are intervals; we know only that the unobserved  $y_j$  is in the interval  $[y_{1j}, y_{2j}]$ . For these observations, the likelihood contribution is  $\Pr(y_{1j} \leq Y_j \leq y_{2j})$ , where  $Y_j$  denotes the random variable representing the dependent variable in the model. Observations  $j \in \mathcal{L}$  are left-censored; we know only that the unobserved  $y_j$  is less than or equal to  $y_{\mathcal{L}j}$ , a censoring value that we do know. Similarly, observations  $j \in \mathcal{R}$  are right-censored; we know only that the unobserved  $y_j$  is greater than or equal to  $y_{\mathcal{R}j}$ . The likelihoods for these censored observations contain terms of the form  $\Pr(Y_j \leq y_{\mathcal{L}j})$  for left-censored data and  $\Pr(Y_j \geq y_{\mathcal{R}j})$  for right-censored data.

The log likelihood is

$$\begin{aligned} \ln L = & -\frac{1}{2} \sum_{j \in \mathcal{C}} w_j \left\{ \left( \frac{y_j - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right)^2 + \log 2\pi\sigma^2 \right\} \\ & + \sum_{j \in \mathcal{L}} w_j \log \Phi \left( \frac{y_{\mathcal{L}j} - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right) \\ & + \sum_{j \in \mathcal{R}} w_j \log \left\{ 1 - \Phi \left( \frac{y_{\mathcal{R}j} - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right) \right\} \\ & + \sum_{j \in \mathcal{I}} w_j \log \left\{ \Phi \left( \frac{y_{2j} - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right) - \Phi \left( \frac{y_{1j} - \mathbf{x}_j\boldsymbol{\beta}}{\sigma} \right) \right\} \end{aligned}$$

where  $\Phi(\cdot)$  is the cumulative standard normal distribution and  $w_j$  is the weight for the  $j$ th observation. If no weights are specified,  $w_j = 1$ . If `awweights` are specified,  $w_j = 1$ , and  $\sigma$  is replaced by  $\sigma/\sqrt{a_j}$  in the above, where  $a_j$  are the `awweights` normalized to sum to  $N$ .

When the `het()` option is specified,  $\sigma$  is modeled as  $\ln(\sigma) = z'_j\boldsymbol{\gamma}$ , where  $z$  represents the variables in `het()` and  $\boldsymbol{\gamma}$  is a vector of the estimated parameters to model the variance.

Note that the likelihood for `intreg` subsumes that of the `tobit` models; see [\[R\] tobit](#).

Maximization is as described in [\[R\] Maximize](#). `intreg` stores the estimated  $\sigma$  in `e(b)` in the log metric; therefore, if you want to provide an initial value for  $\sigma$  or to specify a constraint on it, ensure you do so on the log scale.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [\[P\] \\_robust](#), particularly *Maximum likelihood estimators* and *Methods and formulas*.

`intreg` also supports estimation with survey data. For details on VCEs with survey data, see [\[SVY\] Variance estimation](#).

## Postestimation commands

The following postestimation commands are available after `intreg`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | linear, censored, and truncated predictions                                                                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`hausman` and `lrtest` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as linear predictions, standard errors, probabilities, and expected values.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] stub* [if] [in] , scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                                       |                                             |
|---------------------------------------|---------------------------------------------|
| <code>xb</code>                       | linear prediction; the default              |
| <code>stdp</code>                     | standard error of the prediction            |
| <code>stdf</code>                     | standard error of the forecast              |
| <code>pr(<i>a</i>,<i>b</i>)</code>    | $\Pr(a < y_j < b)$                          |
| <code>e(<i>a</i>,<i>b</i>)</code>     | $E(y_j   a < y_j < b)$                      |
| <code>ystar(<i>a</i>,<i>b</i>)</code> | $E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\}$ |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing (*a* ≥ .) means  $-\infty$ , and *b* missing (*b* ≥ .) means  $+\infty$ ; see [U] 12.2.1 Missing values.

## Options for predict

Main

`xb`, the default, calculates the linear prediction.

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas* in [R] [regress postestimation](#).

`pr(a,b)` calculates  $\Pr(a < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < b)$ , the probability that  $y_j|\mathbf{x}_j$  would be observed in the interval  $(a,b)$ .

$a$  and  $b$  may be specified as numbers or variable names;  $lb$  and  $ub$  are variable names;

`pr(20,30)` calculates  $\Pr(20 < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < 30)$ ;

`pr(lb,ub)` calculates  $\Pr(lb < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < ub)$ ; and

`pr(20,ub)` calculates  $\Pr(20 < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < ub)$ .

$a$  missing ( $a \geq .$ ) means  $-\infty$ ; `pr(.,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < 30)$ ;

`pr(lb,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < 30)$  in observations for which  $lb \geq .$

and calculates  $\Pr(lb < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < 30)$  elsewhere.

$b$  missing ( $b \geq .$ ) means  $+\infty$ ; `pr(20,.)` calculates  $\Pr(+\infty > \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j > 20)$ ;

`pr(20,ub)` calculates  $\Pr(+\infty > \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j > 20)$  in observations for which  $ub \geq .$

and calculates  $\Pr(20 < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < ub)$  elsewhere.

`e(a,b)` calculates  $E(\mathbf{x}_j\boldsymbol{\beta} + \epsilon_j | a < \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j < b)$ , the expected value of  $y_j|\mathbf{x}_j$  conditional on  $y_j|\mathbf{x}_j$  being in the interval  $(a,b)$ , meaning that  $y_j|\mathbf{x}_j$  is truncated.

$a$  and  $b$  are specified as they are for `pr()`.

`ystar(a,b)` calculates  $E(y_j^*)$ , where  $y_j^* = a$  if  $\mathbf{x}_j\boldsymbol{\beta} + \epsilon_j \leq a$ ,  $y_j^* = b$  if  $\mathbf{x}_j\boldsymbol{\beta} + \epsilon_j \geq b$ , and  $y_j^* = \mathbf{x}_j\boldsymbol{\beta} + \epsilon_j$  otherwise, meaning that  $y_j^*$  is censored.  $a$  and  $b$  are specified as they are for `pr()`.

`nooffset` is relevant only if you specified `offset(varname)`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j\boldsymbol{\beta}$  rather than as  $\mathbf{x}_j\boldsymbol{\beta} + \text{offset}_j$ .

`scores` calculates equation-level score variables.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{x}_j\boldsymbol{\beta})$ .

The second new variable will contain  $\partial \ln L / \partial \ln \sigma$ .

# margins

## Description for margins

`margins` estimates margins of response for linear predictions, probabilities, and expected values.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>                      | Description                                 |
|---------------------------------------|---------------------------------------------|
| <code>xb</code>                       | linear prediction; the default              |
| <code>pr(<i>a</i>,<i>b</i>)</code>    | $\Pr(a < y_j < b)$                          |
| <code>e(<i>a</i>,<i>b</i>)</code>     | $E(y_j   a < y_j < b)$                      |
| <code>ystar(<i>a</i>,<i>b</i>)</code> | $E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\}$ |
| <code>stdp</code>                     | not allowed with <code>margins</code>       |
| <code>stdf</code>                     | not allowed with <code>margins</code>       |

Statistics not allowed with `margins` are functions of stochastic quantities other than `e(b)`.

For the full syntax, see [\[R\] margins](#).

## Remarks and examples

### ▷ Example 1: Marginal predictions

Continuing with [example 1](#) of [R] [intreg](#), we compute women's expected wages conditional on a woman's wage being higher than \$5,000. To do this, we can use the  $e(a, b)$  option.

```
. use https://www.stata-press.com/data/r19/womenwage2
(Wages of women, fictional data)
. intreg wage1 wage2 age c.age#c.age i.nev_mar i.rural school tenure
(output omitted)
. predict w1, e(5,.)
. summarize w1
```

| Variable | Obs | Mean     | Std. dev. | Min      | Max      |
|----------|-----|----------|-----------|----------|----------|
| w1       | 488 | 18.02362 | 4.583738  | 8.717687 | 35.31161 |

The predicted wages range from \$8,718 to \$35,312.

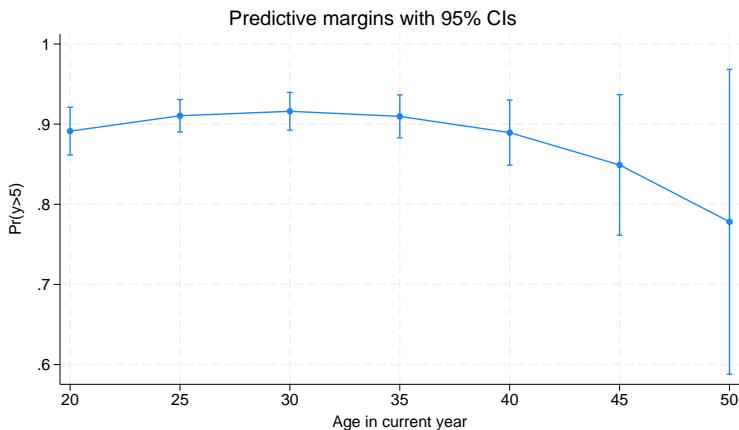

We can also examine whether the probability of earning more than \$5,000 varies with age. We can use `margins` to compute the marginal means of the predicted probabilities at different ages.

```
. margins, predict(pr(5,)) at(age=(20(5)50))
Predictive margins Number of obs = 488
Model VCE: OIM
Expression: Pr(y>5), predict(pr(5,))
1._at: age = 20
2._at: age = 25
3._at: age = 30
4._at: age = 35
5._at: age = 40
6._at: age = 45
7._at: age = 50
```

| _at | Delta-method |           |       |       |                      |
|-----|--------------|-----------|-------|-------|----------------------|
|     | Margin       | std. err. | z     | P> z  | [95% conf. interval] |
| 1   | .8912598     | .0151773  | 58.72 | 0.000 | .8615127 .9210068    |
| 2   | .9104568     | .0103467  | 87.99 | 0.000 | .8901775 .930736     |
| 3   | .9160005     | .0120025  | 76.32 | 0.000 | .892476 .9395251     |
| 4   | .9096667     | .0136693  | 66.55 | 0.000 | .8828753 .9364581    |
| 5   | .8894289     | .0206992  | 42.97 | 0.000 | .8488593 .9299985    |
| 6   | .8491103     | .0447429  | 18.98 | 0.000 | .7614159 .9368048    |
| 7   | .7781644     | .0970557  | 8.02  | 0.000 | .5879387 .9683902    |

We can visualize these results by using marginsplot:

```
. marginsplot
Variables that uniquely identify margins: age
```

The probability increases until age 30 and decreases thereafter.

## Description

`ivfprobit` fits a model for a fractional dependent variable, such as a rate or proportion, where one or more of the covariates are endogenous. The dependent variable must be greater than or equal to 0 and less than or equal to 1. `ivfprobit` assumes all endogenous covariates are continuous.

## Quick start

Fractional probit regression of  $y_1$  on  $x$  and endogenous regressor  $y_2$  that is instrumented using  $z$

```
ivfprobit y1 x (y2 = z)
```

Same as above, but with endogenous regressors  $y_2$  and  $y_3$ , using  $z_1$ ,  $z_2$ , and  $z_3$  as instruments

```
ivfprobit y1 x (y2 y3 = z1 z2 z3)
```

## Menu

Statistics > Endogenous covariates > Fractional probit with endogenous covariates

## Syntax

```
ivfprobit depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight] [, options]
```

*varlist*<sub>1</sub> is the list of exogenous variables.

*varlist*<sub>2</sub> is the list of endogenous variables.

*varlist*<sub>iv</sub> is the list of exogenous variables used with *varlist*<sub>1</sub> as instruments for *varlist*<sub>2</sub>.

`bootstrap`, `by`, `collect`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] `svy`.

`fweights`, `iweights`, and `pweights` are allowed. See [U] 11.1.6 `weight`.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`noconstant`, `constraints(numlist)`; see [R] [Estimation options](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. The default is not to show these parameter estimates.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#).

The following option is available with `ivfprobit` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

*Model setup*

*Model identification*

## Model setup

`ivfprobit` fits models for fractional dependent variables when one or more of the covariates is endogenous. Fractional variables can take any value in the interval  $[0, 1]$ ; thus, `ivfprobit` is useful for modeling outcomes such as rates and proportions.

Formally, we can write the model fit by `ivfprobit` as

$$\begin{aligned} E(y_{1i} | \mathbf{x}_{1i}, \mathbf{x}_{2i}, \mathbf{y}_{2i}, u_i) &= \Phi(\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i) \\ \mathbf{y}_{2i} &= \mathbf{x}_{i1}\boldsymbol{\Pi}_1 + \mathbf{x}_{i2}\boldsymbol{\Pi}_2 + v_i \end{aligned} \quad (1)$$

where subscript  $i$  denotes the observation,  $\mathbf{y}_{2i}$  is a  $1 \times p$  vector of continuous endogenous variables,  $\mathbf{x}_{1i}$  is a  $1 \times k_1$  vector of exogenous covariates, and  $\mathbf{x}_{2i}$  is a  $1 \times k_2$  vector of excluded instruments. Endogeneity arises from the possible correlation between  $u_i$  and  $v_i$ . The coefficients in vectors  $\boldsymbol{\beta}$  and  $\boldsymbol{\gamma}$  are the parameters of interest. Matrices  $\boldsymbol{\Pi}_1$  and  $\boldsymbol{\Pi}_2$  contain the coefficients of the first stage for the reduced-form equation.

To obtain parameter estimates, `ivfprobit` maximizes the same likelihood as `ivprobit` but does not require a binary dependent variable and does not require the joint density of the errors in the model to be specified correctly; see [R] `ivprobit` for more information. `ivfprobit` fits the model via quasilielihood estimation rather than maximum likelihood estimation. The key insight behind quasilielihood estimation is that we do not need to know the true distribution of the entire model to obtain consistent parameter estimates. In fact, the only requirement is the correct specification of the conditional mean given in (1) after integrating over  $u_i$ . Specifying the full distribution of the model correctly is required only if we want to obtain asymptotically efficient standard errors from maximum likelihood estimation.

`ivfprobit` does not assume that the true model is a probit model that accounts for endogeneity, such as the one fit by `ivprobit`. Therefore, the standard errors provided by maximum likelihood estimation are not appropriate. Instead, `ivfprobit` takes the maximum quasilielihood approach and reports robust standard errors by default.

For further discussion on quasilielihood estimation in the context of fractional regression, see [Papke and Wooldridge \(1996\)](#) and [Wooldridge \(2010\)](#).

### ▷ Example 1

We use a corporate 401(k) participation dataset and fit a fractional probit regression of the 401(k) participation rate (`prate`), on corporate employment size (`ltotemp`) and its square, an indicator of whether the 401(k) is the sole pension plan (`sole`), and plan matching rate (`mrate`). The plan matching rate is endogenous and is instrumented using the age of the plan (`age`) and its square.

Our outcome variable `prate` has values between 0 and 1, including 1,351 firms with participation rates of 1. We assume that the functional form of the expected participation rate, after integrating over  $u_i$ , is a cumulative normal density as in (1).

We use `ivfprobit` to fit the fractional probit model, accounting for endogeneity of `mrate`.

```
. use https://www.stata-press.com/data/r19/401k
(Firm-level data on 401k participation)
. ivfprobit prate c.ltotemp#c.ltotemp 1.sole (mrate = c.age#c.age)

Fitting exogenous fractional probit model:
Iteration 0: Log pseudolikelihood = -1769.7046
Iteration 1: Log pseudolikelihood = -1675.4223
Iteration 2: Log pseudolikelihood = -1674.7663
Iteration 3: Log pseudolikelihood = -1674.7661
Iteration 4: Log pseudolikelihood = -1674.7661

Fitting full model:
Iteration 0: Log pseudolikelihood = -3712.498
Iteration 1: Log pseudolikelihood = -3712.4767
Iteration 2: Log pseudolikelihood = -3712.4767

Fractional probit model with endogenous regressors

Log pseudolikelihood = -3712.4767
Number of obs = 4,075
Wald chi2(4) = 907.06
Prob > chi2 = 0.0000
```

| sd(e.mrate)               | .3989664    | .0061807            |       |       | .3870345             | .4112661  |

```
Wald test of exogeneity: chi2(1) = 102.40
Prob > chi2 = 0.0000
Endogenous: mrate
Exogenous: ltotemp c.ltotemp#c.ltotemp 1.sole age c.age#c.age
```

We find a positive effect of `mrate` on the participation rate. Additionally, we see that the correlation between the unobservables, `corr(e.mrate, e.prate)`, is different from zero. This means there is evidence to support our endogeneity conjecture.

◀

## Model identification

As in the basic linear instrumental-variables model, the order condition for identification requires that the number of excluded exogenous variables (that is, the additional instruments) be at least as great as the number of included endogenous variables ( $k_2 \geq p$ ). `ivfprobit` checks this for you and issues an error message if the order condition is not met.

`ivfprobit`, like `probit` and `ivprobit`, checks the exogenous and endogenous variables to see if any of them predict the outcome variable perfectly. It will drop any offending variables and observations and then fit the model on the remaining data. Instruments that are perfect predictors do not affect estimation, so they are not checked. See *Model identification* in [R] `probit` for more information.

## Stored results

`ivfprobit` stores the following in `e()`:

### Scalars

| <code>e(footnote)</code>   | program used to implement the footnote display                           |
| <code>e(marginsok)</code>  | predictions allowed by margins                                           |
| <code>e(asbalanced)</code> | factor variables <code>fvset</code> as <code>asbalanced</code>           |
| <code>e(asobserved)</code> | factor variables <code>fvset</code> as <code>asobserved</code>           |

### Matrices

|                              |                                              |
|------------------------------|----------------------------------------------|
| <code>e(b)</code>            | coefficient vector                           |
| <code>e(Cns)</code>          | constraints matrix                           |
| <code>e(ilog)</code>         | iteration log (up to 20 iterations)          |
| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(Sigma)</code>        | $\Sigma$                                     |
| <code>e(V)</code>            | variance-covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

### Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

Matrices

`r(table)`

matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

See *Methods and formulas* in [R] [ivprobit](#).

## Postestimation commands

The following postestimation commands are of special interest after `ivfprobit`:

| Command                        | Description                                                                                        |
|--------------------------------|----------------------------------------------------------------------------------------------------|
| <code>estat correlation</code> | report the correlation matrix of the errors of the dependent variable and the endogenous variables |
| <code>estat covariance</code>  | report the covariance matrix of the errors of the dependent variable and the endogenous variables  |

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | conditional means, linear predictions, etc.                                                                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\* `forecast` is not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as conditional means, linear predictions, and standard errors.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic asfmethod]
```

```
predict [type] {stub* | newvarlist} [if] [in], scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                   |                                         |
|-------------------|-----------------------------------------|
| <code>cm</code>   | conditional mean; the default           |
| <code>xb</code>   | linear prediction                       |
| <code>stdp</code> | standard error of the linear prediction |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

| <i>asfmethod</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                       |                                          |
|-----------------------|------------------------------------------|
| <code>asf</code>      | average structural function; the default |
| <code>fixedasf</code> | fixed average structural function        |

## Options for predict

Main

`cm`, the default, calculates the conditional mean.

`xb` calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`asf` and `fixedasf` determine how the average structural function (ASF) of the conditional mean is computed. These options are not allowed with `xb` or `stdp`.

`asf` is the default estimator when the `cm` statistic is specified. `asf` computes the ASF of the conditional mean. It is the prediction conditional on the errors of the endogenous variable equations. Put another way, it is the conditional mean accounting for the correlation of the endogenous covariates with the errors of the main equation. Derivatives and contrasts based on `asf` have a structural interpretation. See [margins](#) below for computing derivatives and contrasts.

`fixedasf` calculates a fixed ASF. It is the prediction using only the coefficients and variables of the outcome equation. `fixedasf` does not condition on the errors of the endogenous variable equations. Contrasts between two fixed counterfactuals averaged over the whole sample have a potential-outcome interpretation. Intuitively, it is as if the values of the covariates were fixed at a value exogenously by fiat. See [margins](#) below for computing derivatives and contrasts.

To be clear, derivatives and contrasts between two fixed counterfactuals using the default `asf` option also have a potential-outcome interpretation. And, unlike `fixedasf`, they retain that interpretation when computed over subpopulations for both linear and nonlinear models.

`scores` calculates the equation-level score variables.

For models with one endogenous regressor, four new variables are created.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{z}_i \boldsymbol{\delta})$ .

The second new variable will contain  $\partial \ln L / \partial (\mathbf{x}_i \boldsymbol{\Pi})$ .

The third new variable will contain  $\partial \ln L / \partial \operatorname{atanh} \rho$ .

The fourth new variable will contain  $\partial \ln L / \partial \ln \sigma$ .

For models with  $p$  endogenous regressors,  $p + \{(p + 1)(p + 2)\} / 2$  new variables are created.

The first new variable will contain  $\partial \ln L / \partial (\mathbf{z}_i \boldsymbol{\delta})$ .

The second through  $(p + 1)$ th new variables will contain  $\partial \ln L / \partial (\mathbf{x}_i \boldsymbol{\Pi}_k)$ ,  $k = 1, \dots, p$ , where  $\boldsymbol{\Pi}_k$  is the  $k$ th column of  $\boldsymbol{\Pi}$ .

The remaining score variables will contain the partial derivatives of  $\ln L$  with respect to  $s_{21}, s_{31}, \dots, s_{p+1,1}, s_{22}, \dots, s_{p+1,2}, \dots, s_{p+1,p+1}$ , where  $s_{m,n}$  denotes the  $(m, n)$  element of the Cholesky decomposition of the error covariance matrix.

# margins

## Description for margins

`margins` estimates margins of response for linear predictions and probabilities.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

---

Main

|                   |                                       |
|-------------------|---------------------------------------|
| <code>cm</code>   | conditional mean; the default         |
| <code>xb</code>   | linear prediction                     |
| <code>stdp</code> | not allowed with <code>margins</code> |

---

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## estat

### Description for estat

`estat correlation` displays the correlation matrix of the errors of the dependent variable and the endogenous variables.

`estat covariance` displays the covariance matrix of the errors of the dependent variable and the endogenous variables.

### Menu for estat

Statistics > Postestimation

### Syntax for estat

*Correlation matrix*

```
estat correlation [, border(bspec) left(#) format(%fmt)]
```

*Covariance matrix*

```
estat covariance [, border(bspec) left(#) format(%fmt)]
```

### Options for estat

#### Main

`border`(*bspec*) sets the border style of the matrix display. The default is `border(all)`.

`left`(#) sets the left indent of the matrix display. The default is `left(2)`.

`format`(%*fmt*) specifies the format for displaying the individual elements of the matrix. The default is `format(%9.0g)`.

## Remarks and examples

Remarks are presented under the following headings:

*Marginal effects*

*Obtaining predicted values*

### Marginal effects

#### ▷ Example 1

We can obtain marginal effects by using the `margins` command after `ivfprobit`. We will calculate average marginal effects by using the 401(k) participation model of [example 1](#) in [\[R\] ivfprobit](#).

```
. use https://www.stata-press.com/data/r19/401k
(Firm-level data on 401k participation)
. ivfprobit prate c.ltotemp##c.ltotemp i.sole (mrate = c.age##c.age)
(output omitted)
. margins, dydx(mrate) predict(cm)

Average marginal effects Number of obs = 4,075
Model VCE: Robust
Expression: Conditional mean of prate, predict(cm)
dy/dx wrt: mrate
```

|       | Delta-method |           | z     | P> z  | [95% conf. interval] |          |
|-------|--------------|-----------|-------|-------|----------------------|----------|
|       | dy/dx        | std. err. |       |       |                      |          |
| mrate | .5288314     | .0442438  | 11.95 | 0.000 | .4421152             | .6155477 |

The marginal effect from `ivfprobit` suggests that a \$1 increase in the matching rate (per dollar) given by employers can increase participation by approximately 50%.

◀

### Obtaining predicted values

After fitting your model with `ivfprobit`, you can obtain the conditional mean, or the linear prediction and its standard error for both the estimation sample and other samples, by using the `predict` command; see [\[U\] 20 Estimation and postestimation commands](#) and [\[R\] predict](#).

### Stored results

`estat correlation` stores the following results in `r()`:

Matrices

`r(corr)` correlation matrix of the errors

`estat covariance` stores the following results in `r()`:

Matrices

`r(cov)` covariance matrix of the errors

## Methods and formulas

Recall that the model fit by `ivfprobit` is given by two equations:

$$\begin{aligned} E[y_{1i} | \mathbf{x}_{1i}, \mathbf{x}_{2i}, y_{2i}, u_i] &= \Phi(\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i) \\ \mathbf{y}_{2i} &= \mathbf{x}_{i1}\boldsymbol{\Pi}_1 + \mathbf{x}_{i2}\boldsymbol{\Pi}_2 + v_i \end{aligned}$$

The linear prediction for observation  $i$  is calculated as  $\mathbf{y}_{2i}\hat{\boldsymbol{\beta}} + \mathbf{x}_{1i}\hat{\boldsymbol{\gamma}}$ . The predicted conditional mean is given by  $\Phi(\hat{m}_i)$ , where  $\Phi(\cdot)$  is the standard normal distribution function and  $\hat{m}_i$  is the plugin estimator of

$$m_i = \frac{\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + \rho v_i / \sigma}{\sqrt{1 - \rho^2}}$$

where  $\sigma$  is the standard deviation of  $v_i$  and  $\rho$  is the correlation coefficient between  $u_i$  and  $v_i$ . The ASF uses  $\hat{m}_i$  instead of  $\mathbf{y}_{2i}\hat{\boldsymbol{\beta}} + \mathbf{x}_{1i}\hat{\boldsymbol{\gamma}}$  to evaluate  $\Phi(\cdot)$  and account for endogeneity in the model. The fixed ASF is evaluated at  $\mathbf{y}_{2i}\hat{\boldsymbol{\beta}} + \mathbf{x}_{1i}\hat{\boldsymbol{\gamma}}$ .

## Description

`ivpoisson` estimates the parameters of a Poisson regression model in which some of the covariates are endogenous. The model is also known as an exponential conditional mean model in which some of the covariates are endogenous. The model may be specified using either additive or multiplicative error terms. The model is frequently used to model count outcomes and is also used to model nonnegative outcome variables.

## Quick start

Two-step GMM estimation of the Poisson regression of  $y_1$  on  $x$  and endogenous regressor  $y_2$  that is instrumented using  $z$

```
ivpoisson gmm y1 x (y2 = z)
```

Same as above, but specify multiplicative errors rather than additive

```
ivpoisson gmm y1 x (y2 = z), multiplicative
```

Use iterative GMM estimation

```
ivpoisson gmm y1 x (y2 = z), igmm
```

Specify a weight matrix that allows for correlation within clusters identified by `cvar`

```
ivpoisson gmm y1 x (y2 = z), wmatrix(cluster cvar)
```

Use the control-function estimator

```
ivpoisson cfunction y1 x (y2 = z)
```

## Menu

Statistics > Endogenous covariates > Poisson model with endogenous covariates

## Syntax

*Generalized method of moments estimator*

```
ivpoisson gmm depvar [varlist1] [(varlist2 = varlistiv)] [if] [in] [weight]
[, reg_err_opt options]
```

*Control-function estimator*

```
ivpoisson cfunction depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight]
[, options]
```

| <i>reg_err_opt</i>                                       | Description                                                                                                                                                                                 |
|----------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Model                                                    |                                                                                                                                                                                             |
| <u>additive</u>                                          | add regression errors to the conditional mean term; the default                                                                                                                             |

\*You can specify at most one of these options.

†These options may be specified only when `igmm` is specified.

`varlist1` and `varlistv` may contain factor variables; see [U] 11.4.3 Factor variables.

`devar`, `varlist1`, `varlist2`, and `varlistv` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayesboot`, `bootstrap`, `by`, `collect`, `jackknife`, `rolling`, and `statsby` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`aweights` are not allowed with the `jackknife` prefix; see [R] `jackknife`.

`aweights`, `fweights`, `iwweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`noconstant`, `exposure(varnamee)`, `offset(varnameo)`; see [R] Estimation options.

`additive`, the default, specifies that the regression errors be added to the conditional mean term and have mean 0.

`multiplicative` specifies that the regression errors be multiplied by the conditional mean term and have mean 1.

`twostep`, `onestep`, and `igmm` specify which estimator is to be used.

`twostep` requests the two-step GMM estimator. `gmm` obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, and then reestimates the parameters based on that weight matrix. `twostep` is the default for `ivpoisson gmm`.

`onestep` requests the one-step GMM estimator. The parameters are estimated based on an initial weight matrix, and no updating of the weight matrix is performed except when calculating the appropriate variance–covariance (VCE) matrix. `onestep` is the default for `ivpoisson cfunction`.

`igmm` requests the iterative GMM estimator. `gmm` obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, reestimates the parameters based on that weight matrix, computes a new weight matrix, and so on, to convergence. Convergence is declared when the relative change in the parameter vector is less than `igmmeps()`, the relative change in the weight matrix is less than `igmmweps()`, or `igmmiterate()` iterations have been completed. Hall (2005, sec. 2.4 and 3.6) mentions that there may be gains to finite-sample efficiency from using the iterative estimator.

### Weight matrix

`wmatrix(wmtype)` specifies the type of weight matrix to be used in conjunction with the two-step and iterated GMM estimators.

Specifying `wmatrix(robust)` requests a weight matrix that is appropriate when the errors are independent but not necessarily identically distributed. `wmatrix(robust)` is the default.

Specifying `wmatrix(cluster clustvar)` requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by `clustvar`.

Specifying `wmatrix(unadjusted)` requests a weight matrix that is suitable when the errors are homoskedastic.

`wmatrix()` cannot be specified if `onestep` is also specified.

`center` requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

`winitial(wmtype[, independent])` specifies the weight matrix to use to obtain the first-step parameter estimates.

Specifying `winitial(unadjusted)` requests a weight matrix that assumes the error functions are independent and identically distributed. This matrix is of the form  $(\mathbf{Z}'\mathbf{Z})^{-1}$ , where  $\mathbf{Z}$  represents all the exogenous regressors and instrumental variables.

`winitial(identity)` requests that the identity matrix be used.

`winitial(matname)` requests that Stata matrix *matname* be used.

Including the `independent` suboption creates a weight matrix that assumes error functions are independent. Elements of the weight matrix corresponding to covariances between any two error functions are set equal to zero. This suboption only applies to `ivpoisson cfunction`.

`winitial(unadjusted)` is the default for `ivpoisson gmm`.

`winitial(unadjusted, independent)` is the default for `ivpoisson cfunction`.

---

#### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

`vce(unadjusted)` specifies that an unadjusted (nonrobust) VCE matrix be used; this, along with the `twostep` option, results in the “optimal two-step GMM” estimates often discussed in textbooks. `vce(unadjusted)` may not be set in `ivpoisson cfunction`.

The default `vcetype` is based on the `wmtype` specified in the `wmatrix()` option. If `wmatrix()` is specified but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior in `ivpoisson gmm` and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`. The default `vcetype` for `ivpoisson cfunction` is `robust`.

Specifying `vce(bootstrap)` or `vce(jackknife)` results in standard errors based on the bootstrap or jackknife, respectively. See [R] [vce\\_option](#), [R] [bootstrap](#), and [R] [jackknife](#) for more information on these VCEs.

The syntax for `vcetypes` is identical to those for `wmatrix()`.

---

#### Reporting

`level(#)`; see [R] [Estimation options](#).

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is,  $e^{\beta_i}$  rather than  $\beta_i$ . Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. `irr` may be specified at estimation or when replaying previously estimated results. `irr` is not allowed with `additive`.

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

## Optimization

`from(initial_values)` specifies the initial values to begin the estimation. You can specify a  $1 \times k$  matrix, where  $k$  is the number of parameters in the model, or you can specify a parameter name, its initial value, another parameter name, its initial value, and so on. For example, to initialize the coefficient for `male` to 1.23 and the constant `_cons` to 4.57, you would type

```
ivpoisson ..., from(male 1.23 _cons 4.57) ...
```

Initial values declared using this option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, `ivpoisson` exits with error code 480. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model. `ivpoisson` ignores the row and column names of the matrix.

`igmmiterate(#)`, `igmmeps(#)`, and `igmmweps(#)` control the iterative process for the iterative GMM estimator for `ivpoisson`. These options can be specified only if you also specify `igmm`.

`igmmiterate(#)` specifies the maximum number of iterations to perform with the iterative GMM estimator. The default is the number set using `set maxiter`, which is 300 by default.

`igmmeps(#)` specifies the convergence criterion used for successive parameter estimates when the iterative GMM estimator is used. The default is `igmmeps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `igmmeps()` and the relative difference between successive estimates of the weight matrix is less than `igmmweps()`.

`igmmweps(#)` specifies the convergence criterion used for successive estimates of the weight matrix when the iterative GMM estimator is used. The default is `igmmweps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `igmmeps()` and the relative difference between successive estimates of the weight matrix is less than `igmmweps()`.

*optimization\_options*: `technique()`, `conv_maxiter()`, `conv_ptol()`, `conv_vtol()`, `conv_nrtol()`, and `tracelevel()`. `technique()` specifies the optimization technique to use; `gn` (the default), `nr`, `dfp`, and `bfgs` are allowed. `conv_maxiter()` specifies the maximum number of iterations; `conv_ptol()`, `conv_vtol()`, and `conv_nrtol()` specify the convergence criteria for the parameters, gradient, and scaled Hessian, respectively. `tracelevel()` allows you to obtain additional details during the iterative process. See [M-5] [optimize\(\)](#).

## Remarks and examples

`ivpoisson` estimates the parameters of a Poisson regression model in which some of the covariates are endogenous. A regressor is endogenous if it is related to the unobserved error term. The model is also known as an exponential conditional mean model in which some of the covariates are endogenous. The model may be specified using either additive or multiplicative error terms.

The model is frequently used to model count outcomes and is also used to model nonnegative outcome variables. Poisson regression is a special exponential conditional mean model. See [R] [poisson](#) for more information on Poisson regression.

The exponential conditional mean model has an error form representation in which the dependent variable  $y$  is a function of the exogenous covariates  $\mathbf{x}$ , endogenous covariates  $\mathbf{y}_2$ , and an error  $\epsilon$ . The covariates  $\mathbf{x}$  are independent of  $\epsilon$ , while  $\mathbf{y}_2$  are not.

`ivpoisson` allows  $\epsilon$  to enter either additively,

$$y_i = \exp(\mathbf{x}'_i \boldsymbol{\beta}_1 + \mathbf{y}'_{2,i} \boldsymbol{\beta}_2) + \epsilon_i$$

or multiplicatively,

$$y_i = \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2)\epsilon_i$$

Mullahy (1997), Cameron and Trivedi (2013), Windmeijer and Santos Silva (1997), and Wooldridge (2010) discuss the generalized method of moments (GMM) estimators implemented in `ivpoisson`. GMM is frequently used in modern econometrics. Many econometric and statistical models can be expressed as conditions on the population moments. The parameter estimates produced by GMM estimators make the sample-moment conditions as true as possible given the data. See [R] `gmm` for further information on GMM estimation and how Stata performs it.

The rest of the discussion is presented under the following headings:

*GMM estimator for additive model*  
*GMM estimator for multiplicative model*  
*CF estimator for multiplicative model*

## GMM estimator for additive model

The GMM estimator uses additional variables, known as instruments and denoted by  $\mathbf{z}_i$ , to specify moment conditions that hold in the population. The GMM parameter estimates make the sample versions of these population-moment conditions as close to true as possible. The instrumental variables are assumed to be correlated with the endogenous covariates  $\mathbf{y}_{2,i}$  but independent of the errors  $\epsilon_i$ .

Under additive errors, the dependent variable  $y_i$  is determined by exogenous covariates  $\mathbf{x}_i$ , endogenous covariates  $\mathbf{y}_{2,i}$ , and zero-mean error  $\epsilon_i$  as

$$y_i = \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2) + \epsilon_i$$

This leads to the following error function

$$u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \beta_1, \beta_2) = y_i - \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2)$$

The population-moment conditions for GMM estimation are  $E\{\tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \beta_1, \beta_2)\} = \mathbf{0}$ , where the vector  $\tilde{\mathbf{z}}_i$  is partitioned as  $(\mathbf{x}'_i, \mathbf{z}'_i)$ . The sample-moment conditions are formed by replacing the expectation with the corresponding sample mean. The GMM estimator solves a minimization problem to make the sample-moment conditions as close to zero as possible. Details on how estimation is performed are given in *Methods and formulas*.

Now, we will demonstrate how `ivpoisson gmm` works in the additive error setting with an example.

### ► Example 1: `ivpoisson gmm` with additive errors

This example uses simulated data based on the following story. A news website randomly samples 500 young adults in a major city. The website wants to model the number of times the sampled individuals visit its website (`visits`) based on their overall time spent on the internet (`time`) and the number of times they receive an ad for the website through email or viewing another website (`ad`). The website also suspects the gender of the individual may matter, so an exogenous dummy variable, `female`, is included in the model.

We suspect time spent on the internet is correlated with unobserved factors that additively affect the number of times an individual visits the website. So we treat `time` as an endogenous regressor. Two instruments are used for this variable. The time spent on the phone (`phone`) is one instrument. The other instrument is the time spent interacting with friends and family that live out of town (`frfam`).

We model the number of visits the website receives using an exponential conditional mean model with additive errors and use `ivpoisson gmm` to estimate the parameters of the regression in the output below. To allow for heteroskedasticity of the errors, we use robust standard errors, which is the default; see *Obtaining standard errors* in [R] `gmm` for a discussion of why robust standard errors is the default.

```
. use https://www.stata-press.com/data/r19/website
(Visits to website)
. ivpoisson gmm visits ad female (time = phone frfam)

Step 1:
Iteration 0: GMM criterion Q(b) = .33829416
Iteration 1: GMM criterion Q(b) = .00362656
Iteration 2: GMM criterion Q(b) = .00131886
Iteration 3: GMM criterion Q(b) = .00131876

Step 2:
Iteration 0: GMM criterion Q(b) = .00027102
Iteration 1: GMM criterion Q(b) = .00025811
Iteration 2: GMM criterion Q(b) = .00025811

Exponential mean model with endogenous regressors
Number of parameters = 4 Number of obs = 500
Number of moments = 5
Initial weight matrix: Unadjusted
GMM weight matrix: Robust
```

| visits | Robust      |           | z     | P> z  | [95% conf. interval] |          |
|--------|-------------|-----------|-------|-------|----------------------|----------|
|        | Coefficient | std. err. |       |       |                      |          |
| time   | .0589294    | .0107942  | 5.46  | 0.000 | .0377732             | .0800857 |
| ad     | .137344     | .010157   | 13.52 | 0.000 | .1174366             | .1572515 |
| female | -.0247707   | .0376218  | -0.66 | 0.510 | -.098508             | .0489666 |
| _cons  | 1.041505    | .0385848  | 26.99 | 0.000 | .9658807             | 1.11713  |

Endogenous: time  
 Exogenous: ad female phone frfam

We find significant coefficients for all covariates but `female`. At fixed values of the other covariates, increased time spent on the internet will raise the expected number of website visits. Receiving additional advertisements will also cause an increase in the expected number of website visits.

## GMM estimator for multiplicative model

Under multiplicative errors, the dependent variable  $y_i$  is determined by exogenous covariates  $\mathbf{x}_i$ , endogenous covariates  $\mathbf{y}_{2,i}$ , and unit-mean errors  $\epsilon_i$  as

$$y_i = \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2)\epsilon_i$$

This setting yields a different error function than the additive error case. This ratio formulation is

$$u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \beta_1, \beta_2) = y_i / \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2) - 1$$

Given the instrumental variables  $\mathbf{z}$ , the population-moment conditions for GMM estimation are  $E\{\tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \beta_1, \beta_2)\} = \mathbf{0}$ . The vector  $\tilde{\mathbf{z}}_i$  is partitioned as  $(\mathbf{x}'_i, \mathbf{z}'_i)$ . Same as above, the sample-moment conditions are the sample analogs of the population-moment conditions, and the GMM estimator solves a minimization problem to make the sample-moment conditions as close to zero as possible. Details on how estimation is performed are given in *Methods and formulas*.

## ► Example 2: ivpoisson gmm with multiplicative errors

In this example, we observe a simulated random sample of 5,000 households. We model the number of trips taken by members of the household in the 24-hour period immediately prior to the interview time by using an exponential conditional mean model with multiplicative errors. Exogenous covariates include the distance to the central business district from the household (*cbd*), the distance from the household to a public transit node (*ptn*), whether there is a full-time worker in the household (*worker*), and whether the examined period is on a weekend (*weekend*). We suspect that the endogenous regressor, the transportation cost of the household in the prior week (*tcost*), is correlated with unobserved factors that affect the number of trips taken. This transportation cost includes gasoline and bus, train tickets, etc.

The ratio of the cost of a public transit day pass in the sampled area to the national average cost of such a pass (*pt*) is also observed. This is used as an instrument for transportation cost.

In the output below, we estimate the parameters of the regression with `ivpoisson gmm`. To allow for heteroskedasticity of the errors, we use robust standard errors, which is the default.

```
. use https://www.stata-press.com/data/r19/trip
(Household trips)

. ivpoisson gmm trips cbd ptn worker weekend (tcost = pt), multiplicative

Step 1:
Iteration 0: GMM criterion Q(b) = .04949852
Iteration 1: GMM criterion Q(b) = .00011194
Iteration 2: GMM criterion Q(b) = 1.563e-08
Iteration 3: GMM criterion Q(b) = 3.685e-16

Step 2:
Iteration 0: GMM criterion Q(b) = 2.287e-16
Iteration 1: GMM criterion Q(b) = 1.342e-31

note: model is exactly identified.

| <i>ptn</i>     | -.0113146   | .0021819  | -5.19 | 0.000 | -.015591             | -.0070383 |
| <i>worker</i>  | .6623018    | .0519909  | 12.74 | 0.000 | .5604015             | .764202   |
| <i>weekend</i> | .3009323    | .0362682  | 8.30  | 0.000 | .2298479             | .3720167  |
| <i>_cons</i>   | .2654423    | .1550127  | 1.71  | 0.087 | -.0383769            | .5692616  |

Endogenous: *tcost*

Exogenous: *cbd ptn worker weekend pt*

We find that all coefficients are significant. At fixed values of the other covariates, we see that additional mileage from the central business district and public transit nodes reduces the expected number of trips taken. Individuals who live farther away from the central business district may still be out of the house the same amount of time, but they will take fewer trips because the transit time has increased. The situation is similar for those who live farther from public transit.

To interpret the other parameters, we will look at the partial effects of their respective independent variables. The partial effects of a change in an independent variable on the modeled conditional expectation function vary over the data because the model is nonlinear. However, under the multiplicative error model, the ratio of the new value to the old value after a discrete change in an independent variable is constant over the data.

Let  $\mathbf{w} = (\mathbf{x}', \mathbf{y}'_2)'$ . If we add 1 to the  $j$ th independent variable in  $\mathbf{w}$ , the functional form of the model implies that

$$\frac{E(y|\mathbf{w}, w_j + 1, \epsilon)}{E(y|\mathbf{w}, w_j, \epsilon)} = \frac{E(y|w_1, \dots, w_j + 1, \dots, w_k, \epsilon)}{E(y|w_1, \dots, w_j, \dots, w_k, \epsilon)} = e^{\beta_j}$$

When  $y$  is a count variable, this normalized effect is called the incidence-rate ratio (IRR) for a one-unit change in  $w_j$ .

More generally, the IRR for a  $\Delta w_j$  change in  $w_j$  is  $e^{\beta_j \Delta w_j}$  under a multiplicative-error exponential conditional mean model. We can calculate incidence-rate ratios for different changes in the covariates by using `lincom`; see [R] [lincom](#).

Here we replay the `ivpoisson` results by typing the command name and we specify the `irr` option to get the incidence-rate ratios. Each significance test for a coefficient equaling zero becomes a test for the incidence-rate ratio equaling one.

```
Note: _cons estimates baseline incidence rate.
Endogenous: tcost
Exogenous: cbd ptn worker weekend pt
```

Holding other covariates and the error constant, the expected number of trips made from houses with a full-time worker is nearly twice that of those houses without a full-time worker. Similarly, the expected number of trips made during a weekend day is close to 35% higher than the expected number of trips made on other days. For each additional dollar of weekly transportation cost, the expected number of household trips is increased by approximately 3.6%.

## CF estimator for multiplicative model

Control-function (CF) estimators can be used to account for endogenous covariates. As [Wooldridge \(2010, sec. 18.5\)](#) describes, CF estimators assume a certain structural relationship between the endogenous covariates and the exogenous covariates and use functions of first-stage parameter estimates to control for the endogeneity in the second stage.

[Wooldridge \(2010, sec. 18.5\)](#) notes that the VCE of the second-stage estimator must be adjusted to account for estimates from the first stage. `ivpoisson cfunction` solves this problem by stacking the moment conditions that define each stage and applying a single GMM estimator. See [Newey \(1984\)](#) and [Wooldridge \(2010, sec. 14.2\)](#) for a description of this technique. No adjustment to the VCE is necessary because there is only one stage.

The CF estimator augments the original multiplicative model with an estimated term that controls for the endogeneity of  $\mathbf{y}_{2,i}$ . When  $\mathbf{y}_{2,i}$  is exogenous, the coefficient on this control term is zero. Let  $\mathbf{z}$  be instrumental variables, and the vector  $\tilde{\mathbf{z}}_i$  be  $(\mathbf{x}'_i, \mathbf{z}'_i)$ .

The augmented model is

$$y_i = \exp(\mathbf{x}'_i\boldsymbol{\beta}_1 + \mathbf{y}'_{2,i}\boldsymbol{\beta}_2 + \mathbf{v}'_i\boldsymbol{\rho} + c_i)$$

where

$$\mathbf{y}_{2,i} = \mathbf{B}\tilde{\mathbf{z}}'_i + \mathbf{v}_i$$

The term  $\mathbf{v}'_i\boldsymbol{\rho}$  controls for the endogeneity of  $\mathbf{y}_{2,i}$ , and we normalize  $E\{\exp(c_i)\} = 1$ . The coefficient vector  $\boldsymbol{\rho}$  measures the strength of the endogeneity of  $\mathbf{y}_{2,i}$ ;  $\mathbf{y}_{2,i}$  is exogenous when  $\boldsymbol{\rho} = \mathbf{0}$ .

`ivpoisson cfunction` estimates  $\boldsymbol{\beta}_1$  and  $\boldsymbol{\beta}_2$  and the auxiliary parameters  $\boldsymbol{\rho}$  and  $\mathbf{B}$  by GMM; see [Methods and formulas](#) for details.

### ► Example 3: Control-function estimator

We return to the [previous example](#), where we estimated the parameters of an exponential conditional mean model for the number of trips taken by a household in a 24-hour period. We will estimate the parameters of the regression with the CF estimator method and compare our results with those obtained with the GMM estimator in [example 2](#).

In the output below, we estimate the parameters of the regression with the `ivpoisson` `cfunction` command.

```
. ivpoisson cfunction trips cbd ptn worker weekend (tcost = pt)
Step 1:

```
Endogenous: tcost
Exogenous: cbd ptn worker weekend pt
```

The output table presents results for the estimated coefficients in each of three equations. First, in the `trips` equation, we see the results for the estimated coefficients in the equation for the dependent variable `trips`. Second, in the `tcost` equation, we see the estimated coefficients in the regression of `tcost` on the instrumental and exogenous variables. Third, the `/c_tcost` ancillary parameter corresponds to the estimate of  $\rho$ , the coefficient on the residual variable included to control for the endogeneity of `tcost`.

We find that all coefficients are significant in the exponential conditional mean equation, `trips`. The coefficient estimates in the `trips` equation are similar to the estimates obtained by the GMM estimator in [example 2](#). That the estimated coefficient on the `tcost` control variable is significantly different from zero suggests that `tcost` is endogenous.

## Stored results

ivpoisson stores the following in `e()`:

### Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in  $\mathbf{r}()$ :

Matrices

$\mathbf{r}(\text{table})$

matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in  $\mathbf{r}()$  are updated when the command is replayed and will be replaced when any  $\mathbf{r}$ -class command is run after the estimation command.

## Methods and formulas

The estimators in `ivpoisson` are GMM estimators that can be expressed in terms of error functions and the instruments that are used to form the moment conditions. When offsets  $o_j^\beta$  are used in the outcome variable equation, the following formulas apply with  $\mathbf{x}'_j\beta_1$  changed to  $\mathbf{x}'_j\beta_1 + o_j^\beta$ .

The error functions for the GMM estimators are given in the text.

Here we provide some details about the form of the error function used by the CF estimator.

Recall that the multiplicative model is

$$y_i = \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2)\epsilon_i$$

We parameterize the endogenous variables in the form

$$\mathbf{y}_{2,i} = \mathbf{B}\tilde{\mathbf{z}}'_i + \mathbf{v}_i$$

This allows us to decompose  $\epsilon_i$  as

$$\epsilon_i = \exp(\mathbf{v}'_i\boldsymbol{\rho} + c_i)$$

Given this setup, we obtain the following conditional mean:

$$E(y|\mathbf{x}_i, \mathbf{z}_i, \mathbf{y}_{2,i}, \mathbf{v}_i) = \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2 + \mathbf{v}'_i\boldsymbol{\rho})$$

We estimate  $\mathbf{v}_i$  as the residuals of the linear regression of  $\mathbf{y}_{2,i}$  on  $\tilde{\mathbf{z}}_i$ . The estimates of  $\mathbf{v}_i$  are used as additional covariates in the exponential conditional mean model for  $y$  to estimate  $\beta_1$ ,  $\beta_2$ , and  $\boldsymbol{\rho}$ . In essence, the estimates of  $\mathbf{v}_i$  control for the endogeneity.

The error functions for the endogenous covariates are defined as

$$\mathbf{u}_{en,i}(\mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i, \mathbf{B}) = \mathbf{y}_{2,i} - \mathbf{B}\tilde{\mathbf{z}}'_i$$

Now, we define the error function for the dependent variable as

$$u_y(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \mathbf{u}_{en,i}, \beta_1, \beta_2, \boldsymbol{\rho}) = y_i / \exp(\mathbf{x}'_i\beta_1 + \mathbf{y}'_{2,i}\beta_2 + \mathbf{u}'_{en,i}\boldsymbol{\rho}) - 1$$

$\mathbf{u}_{en,i}$  will be vector valued if we have multiple endogenous covariates  $\mathbf{y}_{2,i}$ . Call the dimension of  $\mathbf{y}_{2,i}$   $g$ .  $\mathbf{u}_{en,i}$  and  $u_{y,i}$  define  $g + 1$  separate error functions. We will use variables  $\tilde{\mathbf{z}}_i$  to instrument each error function in  $\mathbf{u}_{en,i}$ . So for error function  $j = 1, \dots, g$ , we have the error function  $u_{en,i,j}$  and the population-moment conditions  $E(\tilde{\mathbf{z}}_i u_{en,i,j}) = \mathbf{0}$ .

We calculate  $\hat{v}_{oi}$  previous to estimation as the residuals of the linear regression of  $y_{2,i}$  on  $\tilde{z}_i$ . We use variables  $x_i$ ,  $y_{2,i}$ , and  $\hat{v}_{oi}$  to instrument the error function  $u_y$ . This leads to the population-moment conditions  $E\{(\mathbf{x}'_i, y'_{2,i}, \hat{v}'_{oi})u_{y,i}\} = \mathbf{0}$

Details of GMM estimation can be found in *Methods and formulas* of [R] **gmm**. Determination of the weight matrix  $\mathbf{W}_N$  is discussed there.

Under the GMM estimation, the GMM estimators  $\hat{\beta}_1$  and  $\hat{\beta}_2$  are the values of  $\beta_1$  and  $\beta_2$  that minimize

$$Q(\beta_1, \beta_2) = \left\{ \frac{1}{N} \sum_i \tilde{z}_i u_i(y_i, \mathbf{x}_i, y_{2,i}, \beta_1, \beta_2) \right\}' \mathbf{W}_N \left\{ \frac{1}{N} \sum_i \tilde{z}_i u_i(y_i, \mathbf{x}_i, y_{2,i}, \beta_1, \beta_2) \right\} \quad (1)$$

for  $q \times q$  weight matrix  $\mathbf{W}_N$ , where  $q$  is the dimension of  $\tilde{z}_i$ . The error functions  $u_i$  were defined in the text.

In the CF method, we have multiple error functions as defined above. We can stack the moment conditions and write them more compactly as  $\mathbf{Z}'_i \mathbf{u}_i(\mathbf{B}, \beta_1, \beta_2, \rho)$ , where

$$\mathbf{Z}_i = \begin{bmatrix} \mathbf{x}'_i & \mathbf{0} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & y'_{2,i} & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \tilde{z}_i & \cdots & \mathbf{0} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \cdots & \tilde{z}_i \end{bmatrix}$$

and

$$\mathbf{u}_i(\mathbf{B}, \beta_1, \beta_2, \rho) = \begin{bmatrix} u_y(y_i, \mathbf{x}_i, y_{2,i}, \mathbf{u}_{en,i}, \beta_1, \beta_2, \rho) \\ \mathbf{u}_{en}(y_{2,i}, \tilde{z}_i, \mathbf{B}) \end{bmatrix}$$

The matrix  $\mathbf{Z}_i$  has  $g + 1$  rows and  $k + gz$  columns, where  $k$  is the number of covariates for  $y_i$  and  $z$  is the number of exogenous covariates in  $\tilde{z}_i$ .

The GMM estimators  $\hat{\mathbf{B}}, \hat{\beta}_1, \hat{\beta}_2$ , and  $\hat{\rho}$  are the values of  $\mathbf{B}, \beta_1, \beta_2$ , and  $\rho$  that minimize

$$Q(\mathbf{B}, \beta_1, \beta_2, \rho) = \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\mathbf{B}, \beta_1, \beta_2, \rho) \right\}' \mathbf{W}_N \left\{ N^{-1} \sum_{i=1}^N \mathbf{Z}'_i \mathbf{u}_i(\mathbf{B}, \beta_1, \beta_2, \rho) \right\} \quad (2)$$

for  $(k + gz) \times (k + gz)$  weight matrix  $\mathbf{W}_N$ .

By default, `ivpoisson` minimizes (1) and (2) using the Gauss–Newton method. See Hayashi (2000, 498) for a derivation. This technique is typically faster than quasi-Newton methods and does not require second-order derivatives.

## Postestimation commands

The following postestimation command is of special interest after `ivpoisson`:

| Command                   | Description                                  |
|---------------------------|----------------------------------------------|
| <code>estat overid</code> | perform test of overidentifying restrictions |

The following standard postestimation commands are also available:

| Command                      | Description                                                                                       |
|------------------------------|---------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                               |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                      |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                |
| <code>estimates</code>       | cataloging estimation results                                                                     |
| <code>etable</code>          | table of estimation results                                                                       |
| <code>forecast</code>        | dynamic forecasts and simulations                                                                 |
| <code>hausman</code>         | Hausman’s specification test                                                                      |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters    |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                           |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters |
| <code>predict</code>         | number of events, linear predictions, residuals, etc.                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions              |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                              |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                |

# predict

## Description for predict

`predict` creates a new variable containing predictions such as numbers of events, linear predictions, and residuals.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

| <i>statistic</i> | Description |

| <code>xbtotal</code>   | linear prediction, using residual estimates for <code>ivpoisson cfunction</code> |
| <code>xb</code>        | linear prediction                                                                |
| <code>residuals</code> | residuals                                                                        |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`n`, the default, calculates the predicted number of events via the exponential-form estimate. This is  $\exp(\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2)$  if neither `offset()` nor `exposure()` was specified,  $\exp(\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2 + \text{offset}_j)$  if `offset()` was specified, or  $\exp(\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2) \times \text{exposure}_j$  if `exposure()` was specified.

After generalized method of moments estimation, the exponential-form estimate is not a consistent estimate of the conditional mean of  $y_j$ , because it is not corrected for  $E(\epsilon_j | \mathbf{y}_{2,j})$ . More details are found in [Methods and formulas](#).

After control-function estimation, we correct the exponential-form estimate for  $E(\epsilon_j | \mathbf{y}_{2,j})$  by using the estimated residuals of  $\mathbf{y}_{2,j}$  and the `c_*` auxiliary parameters. This supplements the direct effect of  $\mathbf{y}_{2,j}$  and  $\mathbf{x}_j$  through  $\beta_1$  and  $\beta_2$  with the indirect effects of  $\mathbf{y}_{2,j}$ ,  $\mathbf{x}_j$ , and the instruments  $\mathbf{z}_j$  through the endogenous error  $\epsilon_j$ . Thus, the exponential-form estimate consistently estimates the conditional mean of  $y_j$ .

`xbtotal` calculates the linear prediction, which is  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2$  if neither `offset()` nor `exposure()` was specified,  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2 + \text{offset}_j$  if `offset()` was specified, or  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2 + \ln(\text{exposure}_j)$  if `exposure()` was specified.

After control-function estimation, the estimate of the linear form  $\mathbf{x}'_j\beta_1$  includes the estimated residuals of the endogenous regressors with coefficients from the `c_*` auxiliary parameters.

`xb` calculates the linear prediction, which is  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2$  if neither `offset()` nor `exposure()` was specified,  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2 + \text{offset}_j$  if `offset()` was specified, or  $\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2 + \ln(\text{exposure}_j)$  if `exposure()` was specified. See `nooffset` below.

`residuals` calculates the residuals. Under additive errors, these are calculated as  $y_j - \exp(\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2)$ . Under multiplicative errors, they are calculated as  $y_j / \exp(\mathbf{x}'_j\beta_1 + \mathbf{y}'_{2,j}\beta_2) - 1$ .

When `offset()` or `exposure()` is specified,  $\mathbf{x}'_j\beta_1$  is not used directly in the residuals.  $\mathbf{x}'_j\beta_1 + \text{offset}_j$  is used if `offset()` was specified.  $\mathbf{x}'_j\beta_1 + \ln(\text{exposure}_j)$  is used if `exposure()` was specified. See `nooffset` below.

After control-function estimation, the estimate of the linear form  $\mathbf{x}'_j\beta_1$  includes the estimated residuals of the endogenous regressors with coefficients from the `c_*` auxiliary parameters.

`nooffset` is relevant only if you specified `offset()` or `exposure()` when you fit the model. It modifies the calculations made by `predict` so that they ignore the offset or exposure variable. `nooffset` removes the offset from calculations involving both the `treat()` equation and the dependent count variable.

## margins

### Description for margins

`margins` estimates margins of response for numbers of events and linear predictions.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

| <code>n</code>         | number of events; the default                                                    |
| <code>xbtotal</code>   | linear prediction, using residual estimates for <code>ivpoisson cfunction</code> |
| <code>xb</code>        | linear prediction                                                                |
| <code>residuals</code> | not allowed with <code>margins</code>                                            |

Statistics not allowed with `margins` are functions of stochastic quantities other than `e(b)`.

For the full syntax, see [R] [margins](#).

## estat

### Description for estat

`estat overid` reports Hansen's  $J$  statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. `ivpoisson gmm` uses GMM estimation to obtain parameter estimates. Under additive and multiplicative errors, Hansen's  $J$  statistic can be accurately reported when more instruments than endogenous regressors are specified. It is not appropriate to report the  $J$  statistic after `ivpoisson cfunction`, because a just-identified model is fit.

If the model is correctly specified in the sense that  $E\{\tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \boldsymbol{\beta})\} = \mathbf{0}$ , then the sample analog to that condition should hold at the estimated value of  $\beta_1$  and  $\beta_2$ . The  $\tilde{\mathbf{z}}_i$  variables are the exogenous regressors  $\mathbf{x}_i$  and instrumental variables  $\mathbf{z}_i$  used in `ivpoisson gmm`. The  $\mathbf{y}_{2,i}$  are the endogenous regressors. The  $u$  function is the error function, which will have a different form for multiplicative and additive errors in the regression.

Hansen's  $J$  statistic is valid only if the weight matrix is optimal, meaning that it equals the inverse of the covariance matrix of the moment conditions. Therefore, `estat overid` only reports Hansen's  $J$  statistic after two-step or iterated estimation or if you specified `winitial(matname)` when calling `ivpoisson gmm`. In the latter case, it is your responsibility to determine the validity of the  $J$  statistic.

### Syntax for estat

`estat overid`

### Remarks and examples

`estat overid` reports Hansen's  $J$  statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. It is not appropriate to use it after `ivpoisson cfunction`, because a just-identified model is fit.

Recall that the GMM criterion function is

$$Q(\boldsymbol{\beta}) = \left\{ \frac{1}{N} \sum_i \tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \boldsymbol{\beta}_1, \boldsymbol{\beta}_2) \right\}' \mathbf{W}_N \left\{ \frac{1}{N} \sum_i \tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \boldsymbol{\beta}_1, \boldsymbol{\beta}_2) \right\}$$

Our  $u$  function within this formula will change depending on whether we use additive or multiplicative errors. The  $\tilde{\mathbf{z}}$  vector contains the exogenous regressors and instrumental variables used. `ivpoisson gmm` estimates regression coefficients to minimize  $Q$ .

Let  $l$  be the dimension of  $\tilde{\mathbf{z}}$  and  $k$  the number of regressors. If  $\mathbf{W}_N$  is an optimal weight matrix, under the null hypothesis  $H_0: E\{\tilde{\mathbf{z}}_i u(y_i, \mathbf{x}_i, \mathbf{y}_{2,i}, \boldsymbol{\beta}_1, \boldsymbol{\beta}_2)\} = \mathbf{0}$ , the test statistic  $J = N \times Q \sim \chi^2(l - k)$ . A large test statistic casts doubt on the null hypothesis.

Because the weight matrix  $\mathbf{W}_N$  must be optimal, `estat overid` works only after the two-step and iterated estimation or if you supplied your own initial weight matrix by using the `winitial(matname)` option of `ivpoisson gmm` and used the one-step estimator.

Often, the overidentifying restrictions test is interpreted as a test of the validity of the instruments  $\mathbf{z}$ . However, other forms of model misspecification can sometimes lead to a significant test statistic. See Hall (2005, sec. 5.1) for a discussion of the overidentifying restrictions test and its behavior in correctly specified and misspecified models.

Note that `ivpoisson gmm` defaults to the two-step estimator when other options are not specified to override the default. Thus, it is appropriate to perform the  $J$  test after the regression of [example 1](#) in [\[R\] ivpoisson](#).

### ▷ Example 1: Specification test

Recall [example 1](#) of [\[R\] ivpoisson](#). We estimated the parameters of an exponential conditional mean model for the number of visits to a website. Additive errors were used. Exogenous regressors included the gender of an individual and the number of ads received from the website.

An endogenous regressor, time spent on the internet, was also included in the model. Two instruments were used. One of the instruments measured the time spent interacting with friends and out-of-town family. The other measured the time spent on the phone.

We will reestimate the parameters of the regression here and then test the specification.

```
. use https://www.stata-press.com/data/r19/website
(Visits to website)
. ivpoisson gmm visits ad female (time = phone frfam)
(output omitted)
. estat overid
Test of overidentifying restriction:
Hansen's J chi2(1) = .129055 (p = 0.7194)
```

We have two instruments for one endogenous variable, so the  $J$  statistic has one degree of freedom. The  $J$  statistic is not significant. We fail to reject the null hypothesis that the model is correctly specified.

## Stored results

`estat overid` stores the following in `r()`:

Scalars

|                      |                                  |
|----------------------|----------------------------------|
| <code>r(J)</code>    | Hansen's $J$ statistic           |
| <code>r(J_df)</code> | $J$ statistic degrees of freedom |
| <code>r(J_p)</code>  | $J$ statistic $p$ -value         |

## Methods and formulas

The vector  $\mathbf{x}_i$  contains the exogenous regressors, and  $\mathbf{z}_i$  the instruments. The vector  $\tilde{\mathbf{z}}_i$  is partitioned as  $(\mathbf{x}_i, \mathbf{z}_i)$ . The vector  $\mathbf{y}_{2,i}$  contains the endogenous regressors.

Under multiplicative errors, the conditional mean of  $y_i$  is

$$\begin{aligned} E(y_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) &= E\{E(y_i | \mathbf{x}_i, \mathbf{y}_{2,i}, \epsilon_i) | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i\} \\ &= E\{\exp(\mathbf{x}'_i \boldsymbol{\beta}_1 + \mathbf{y}'_{2,i} \boldsymbol{\beta}_2) \epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i\} \\ &= \exp(\mathbf{x}'_i \boldsymbol{\beta}_1 + \mathbf{y}'_{2,i} \boldsymbol{\beta}_2) E(\epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) \end{aligned}$$

Under the CF estimator,

$$\begin{aligned} E(\epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) &= E\{E(\epsilon_i | \mathbf{v}_i, c_i) | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i\} \\ &= E\{\exp(\mathbf{v}'_i \boldsymbol{\rho} + c_i) | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i\} \\ &= \exp\{(\mathbf{y}_{2,i} - \mathbf{B}\tilde{\mathbf{z}}_i)' \boldsymbol{\rho}\} E(c_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) \\ &= \exp\{(\mathbf{y}_{2,i} - \mathbf{B}\tilde{\mathbf{z}}_i)' \boldsymbol{\rho}\} \end{aligned}$$

Thus under the CF estimator, we estimate the conditional mean of  $y_i$  as

$$E(y_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) = \exp(\mathbf{x}'_i \boldsymbol{\beta}_1 + \mathbf{y}'_{2,i} \boldsymbol{\beta}_2 + (\mathbf{y}_{2,i} - \mathbf{B}\tilde{\mathbf{z}}_i)' \boldsymbol{\rho})$$

The CF estimator explicitly models the functional form of the endogeneity of  $\mathbf{y}_{2,i}$  and  $\epsilon_i$  with the instruments and exogenous regressors  $\tilde{\mathbf{z}}_i$ . This allows it to correct the exponential-form estimator for the  $E(\epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i)$  term.

In contrast, the GMM estimator does not model the functional form of the endogeneity of  $\mathbf{y}_{2,i}$  and  $\epsilon_i$ . Therefore,  $E(\epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i)$  is not estimated, and the exponential-form estimator under GMM estimation simply ignores this term. Noting that because  $\tilde{\mathbf{z}}_i$  and  $\epsilon_i$  are independent,  $E(\epsilon_i | \mathbf{y}_{2,i}, \tilde{\mathbf{z}}_i) = E(\epsilon_i | \mathbf{y}_{2,i})$ , we can obviously see that ignoring the term will lead to inconsistent estimation of the conditional mean of  $y_i$ .  $y_{2,i}$  and  $\epsilon_i$  are not independent, so  $E(\epsilon_i | y_{2,i})$  may vary based on  $y_{2,i}$ .

In the additive errors setting, a similar derivation will show that the exponential-form estimator obtained from GMM estimation is inconsistent for the conditional mean of  $y_i$ .

## Description

`ivprobit` fits models for binary dependent variables where one or more of the covariates are endogenous and errors are normally distributed. By default, `ivprobit` uses maximum likelihood, but Newey's (1987) minimum  $\chi^2$  (two-step) estimator can be requested. Both estimators assume that the endogenous covariates are continuous and so are not appropriate for use with discrete endogenous covariates.

## Quick start

Probit regression of  $y_1$  on  $x$  and endogenous regressor  $y_2$  that is instrumented using  $z$

```
ivprobit y1 x (y2 = z)
```

With robust standard errors

```
ivprobit y1 x (y2 = z), vce(robust)
```

Use Newey's two-step estimator

```
ivprobit y1 x (y2 = z), twostep
```

Same as above, and show first-stage regression results

```
ivprobit y1 x (y2 = z), twostep first
```

## Menu

Statistics > Endogenous covariates > Probit model with endogenous covariates

## Syntax

Maximum likelihood estimator

```
ivprobit depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight] [, mle_options]
```

Two-step estimator

```
ivprobit depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight] , twostep
[tse_options]
```

*varlist*<sub>1</sub> is the list of exogenous variables.

*varlist*<sub>2</sub> is the list of endogenous variables.

*varlist*<sub>iv</sub> is the list of exogenous variables used with *varlist*<sub>1</sub> as instruments for *varlist*<sub>2</sub>.

\*`twostep` is required.

`varlist1` and `varlistiv` may contain factor variables; see [U] 11.4.3 **Factor variables**.

`devar`, `varlist1`, `varlist2`, and `varlistiv` may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

`bootstrap`, `by`, `collect`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 **Prefix commands**. `fp` is allowed with the maximum likelihood estimator.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`vce()`, `first`, `twostep`, and `weights` are not allowed with the `svy` prefix; see [SVY] **svy**.

`fweights`, `iweights`, and `pweights` are allowed with the maximum likelihood estimator. `fweights` are allowed with Newey's two-step estimator. See [U] 11.1.6 **weight**.

`coeflegend` does not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options for ML estimator

### Model

`mle` requests that the conditional maximum-likelihood estimator be used. This is the default.

`asis` requests that all specified variables and observations be retained in the maximization process. This option is typically not used and may introduce numerical instability. Normally, `ivprobit` omits any endogenous or exogenous variables that perfectly predict success or failure in the dependent variable.

The associated observations are also excluded. For more information, see *Model identification* in [R] **probit**.

`constraints(constraints)`; see [R] **Estimation options**.

### SE/Robust

`vce(vctype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] *vce\_option*.

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, `first` shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the probit equation. The default is not to show these parameter estimates.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

## Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#).

The following option is available with `ivprobit` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Options for two-step estimator

## Model

`twostep` is required and requests that Newey's (1987) efficient two-step estimator be used to obtain the coefficient estimates.

`asis` requests that all specified variables and observations be retained in the maximization process. This option is typically not used and may introduce numerical instability. Normally, `ivprobit` omits any endogenous or exogenous variables that perfectly predict success or failure in the dependent variable. The associated observations are also excluded. For more information, see [Model identification](#) in [R] [probit](#).

## SE

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`twostep`) and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, `first` shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the probit equation. The default is not to show these parameter estimates.

*display\_options*: `noc1`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

The following option is available with `ivprobit` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

[Model setup](#)

[Model identification](#)

### Model setup

`ivprobit` fits models with dichotomous dependent variables and endogenous covariates. You can use it to fit a probit model when you suspect that one or more of the covariates are correlated with the error term. `ivprobit` is to probit modeling what `ivregress` is to linear regression analysis; see [R] [ivregress](#) for more information.

Formally, the model is

$$\begin{aligned}y_{1i}^* &= \mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i \\ \mathbf{y}_{2i} &= \mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2 + \mathbf{v}_i\end{aligned}$$

where  $i = 1, \dots, N$ ,  $\mathbf{y}_{2i}$  is a  $1 \times p$  vector of endogenous variables,  $\mathbf{x}_{1i}$  is a  $1 \times k_1$  vector of exogenous variables,  $\mathbf{x}_{2i}$  is a  $1 \times k_2$  vector of additional instruments, and the equation for  $\mathbf{y}_{2i}$  is written in reduced form. By assumption,  $(u_i, \mathbf{v}_i) \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ , where  $\sigma_{11}$  is normalized to one to identify the model.  $\boldsymbol{\beta}$  and  $\boldsymbol{\gamma}$  are vectors of structural parameters, and  $\boldsymbol{\Pi}_1$  and  $\boldsymbol{\Pi}_2$  are matrices of reduced-form parameters. This is a recursive model:  $\mathbf{y}_{2i}$  appears in the equation for  $y_{1i}^*$ , but  $y_{1i}^*$  does not appear in the equation for  $\mathbf{y}_{2i}$ . We do not observe  $y_{1i}^*$ ; instead, we observe

$$y_{1i} = \begin{cases} 0 & y_{1i}^* < 0 \\ 1 & y_{1i}^* \geq 0 \end{cases}$$

The order condition for identification of the structural parameters requires that  $k_2 \geq p$ . Presumably,  $\boldsymbol{\Sigma}$  is not block diagonal between  $u_i$  and  $\mathbf{v}_i$ ; otherwise,  $\mathbf{y}_{2i}$  would not be endogenous.

### □ Technical note

This model is derived under the assumption that  $(u_i, \mathbf{v}_i)$  is independent and identically distributed multivariate normal for all  $i$ . The `vce(cluster clustvar)` option can be used to control for a lack of independence. As with most probit models, if  $u_i$  is heteroskedastic, point estimates will be inconsistent. □

## ▶ Example 1

We have hypothetical data on 500 two-parent households, and we wish to model whether the woman is employed. We have a variable, `fem_work`, that is equal to 1 if she has a job and 0 otherwise. Her decision to work is a function of the number of children at home (`kids`), number of years of schooling completed (`fem_educ`), and other household income measured in thousands of dollars (`other_inc`). We suspect that unobservable shocks affecting the woman's decision to hold a job also affect the household's other income. Therefore, we treat `other_inc` as endogenous. As an instrument, we use the number of years of schooling completed by the man (`male_educ`).

The syntax for specifying the exogenous, endogenous, and instrumental variables is identical to that used in `ivregress`; see [R] [ivregress](#) for details.

```
. use https://www.stata-press.com/data/r19/laborsup

```
Wald test of exogeneity (corr = 0): chi2(1) = 6.70 Prob > chi2 = 0.0096
Endogenous: other_inc
Exogenous: fem_educ kids male_educ
```

`ivprobit` used the default maximum likelihood estimator. The header of the output contains the sample size as well as a Wald statistic and  $p$ -value for the test of the hypothesis that all the slope coefficients are jointly zero. Below, the table of coefficients, Stata reminds us that the endogenous variable is `other_inc` and that `fem_educ`, `kids`, and `male_educ` were used as instruments.

At the bottom of the output is a Wald test of the exogeneity of the endogenous variables. We reject the null hypothesis of no endogeneity. If there is no endogeneity, a standard probit regression would be preferable (see [R] [probit](#)).

Below we fit our model with Newey's (1987) minimum  $\chi^2$  estimator using the twostep option.

## ▷ Example 2

Refitting our labor-supply model with the two-step estimator yields

```
. ivprobit fem_work fem_educ kids (other_inc = male_educ), twostep
Checking reduced-form model...
Two-step probit with endogenous regressors Number of obs = 500
 Wald chi2(3) = 93.97
 Prob > chi2 = 0.0000
```

|           | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |           |
|-----------|-------------|-----------|-------|-------|----------------------|-----------|
| other_inc | -.058473    | .0093364  | -6.26 | 0.000 | -.0767719            | -.040174  |
| fem_educ  | .227437     | .0281628  | 8.08  | 0.000 | .1722389             | .282635   |
| kids      | -.1961748   | .0496323  | -3.95 | 0.000 | -.2934522            | -.0988973 |
| _cons     | .3956061    | .4982649  | 0.79  | 0.427 | -.5809752            | 1.372187  |

```
Wald test of exogeneity: chi2(1) = 6.50 Prob > chi2 = 0.0108
Endogenous: other_inc
Exogenous: fem_educ kids male_educ
```

All the coefficients have the same signs as their counterparts in the maximum likelihood model. The Wald test at the bottom of the output confirms our earlier finding of endogeneity.

◀

## □ Technical note

In a standard probit model, the error is assumed to have a variance of 1. In the probit model with endogenous covariates, we assume that  $(u_i, \mathbf{v}_i)$  is multivariate normal with covariance matrix

$$\text{Var}(u_i, \mathbf{v}_i) = \Sigma = \begin{bmatrix} 1 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}$$

From the properties of the multivariate normal distribution, it follows that  $\text{Var}(u_i | \mathbf{v}_i) = 1 - \Sigma'_{21} \Sigma_{22}^{-1} \Sigma_{21}$ . Newey's estimator and other two-step probit estimators yield estimates of  $\beta/\sigma$  and  $\gamma/\sigma$ , where  $\sigma$  is the square root of  $\text{Var}(u_i | \mathbf{v}_i)$ , instead of estimates of  $\beta$  and  $\gamma$ . Hence, we cannot directly compare the estimates obtained from Newey's estimator with those obtained from maximum likelihood, which estimate  $\beta$ ,  $\gamma$ , and  $\sigma$  separately. See Wooldridge (2010, 585–594) for a discussion about the interpretation of the estimates and the computation of marginal effects of two-step probit estimators under endogeneity. □

## Model identification

As in the linear simultaneous-equation model, the order condition for identification requires that the number of excluded exogenous variables (that is, the additional instruments) be at least as great as the number of included endogenous variables. `ivprobit` checks this for you and issues an error message if the order condition is not met.

Like `probit`, `logit`, and `logistic`, `ivprobit` checks the exogenous and endogenous variables to see if any of them predict the outcome variable perfectly. It will then omit offending variables and observations and fit the model on the remaining data. Instruments that are perfect predictors do not affect estimation, so they are not checked. See [Model identification](#) in [R] `probit` for more information.

ivprobit will also occasionally display messages such as

Note: 4 failures and 0 successes completely determined.

For an explanation of this message, see [R] [logit](#).

## Stored results

ivprobit, mle stores the following in `e()`:

Functions  
 e(sample) marks estimation sample

In addition to the above, the following is stored in `r()`:

Matrices  
 r(table) matrix containing the coefficients with their standard errors, test statistics,  $p$ -values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Fitting limited-dependent variable models with endogenous covariates has received considerable attention in the econometrics literature. Building on the results of Amemiya (1978, 1979), Newey (1987) developed an efficient method of estimation that encompasses both Rivers and Vuong's (1988) simultaneous-equations probit model and Smith and Blundell's (1986) simultaneous-equations tobit model. An efficient alternative to two-step estimation, and `ivprobit`'s default, is to use maximum likelihood. For compactness, we write the model as

$$y_{1i}^* = \mathbf{z}_i \boldsymbol{\delta} + u_i \quad (1)$$

$$\mathbf{y}_{2i} = \mathbf{x}_i \boldsymbol{\Pi} + v_i \quad (2)$$

where  $\mathbf{z}_i = (\mathbf{y}_{2i}, \mathbf{x}_{1i})$ ,  $\mathbf{x}_i = (\mathbf{x}_{1i}, \mathbf{x}_{2i})$ ,  $\boldsymbol{\delta} = (\boldsymbol{\beta}', \boldsymbol{\gamma}')$ , and  $\boldsymbol{\Pi} = (\boldsymbol{\Pi}'_1, \boldsymbol{\Pi}'_2)'$ .

Deriving the likelihood function is straightforward because we can write the joint density  $f(y_{1i}, \mathbf{y}_{2i} | \mathbf{x}_i)$  as  $f(y_{1i} | \mathbf{y}_{2i}, \mathbf{x}_i) f(\mathbf{y}_{2i} | \mathbf{x}_i)$ . When there is an endogenous regressor, the log likelihood for observation  $i$  is

$$\ln L_i = w_i \left[ y_{1i} \ln \Phi(m_i) + (1 - y_{1i}) \ln \{1 - \Phi(m_i)\} + \ln \phi \left( \frac{y_{2i} - \mathbf{x}_i \boldsymbol{\Pi}}{\sigma} \right) - \ln \sigma \right]$$

where

$$m_i = \frac{\mathbf{z}_i \boldsymbol{\delta} + \rho (y_{2i} - \mathbf{x}_i \boldsymbol{\Pi}) / \sigma}{(1 - \rho^2)^{\frac{1}{2}}}$$

$\Phi(\cdot)$  and  $\phi(\cdot)$  are the standard normal distribution and density functions, respectively;  $\sigma$  is the standard deviation of  $v_i$ ;  $\rho$  is the correlation coefficient between  $u_i$  and  $v_i$ ; and  $w_i$  is the weight for observation  $i$  or one if no weights were specified. Instead of estimating  $\sigma$  and  $\rho$ , we estimate  $\ln \sigma$  and  $\operatorname{atanh} \rho$ , where

$$\operatorname{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

For multiple endogenous covariates, let

$$\operatorname{Var}(u_i, v_i) = \boldsymbol{\Sigma} = \begin{bmatrix} 1 & \boldsymbol{\Sigma}'_{21} \\ \boldsymbol{\Sigma}_{21} & \boldsymbol{\Sigma}_{22} \end{bmatrix}$$

As in any probit model, we have imposed the normalization  $\operatorname{Var}(u_i) = 1$  to identify the model. The log likelihood for observation  $i$  is

$$\ln L_i = w_i \left[ y_{1i} \ln \Phi(m_i) + (1 - y_{1i}) \ln \{1 - \Phi(m_i)\} + \ln f(\mathbf{y}_{2i} | \mathbf{x}_i) \right]$$

where

$$\ln f(\mathbf{y}_{2i} | \mathbf{x}_i) = -\frac{p}{2} \ln 2\pi - \frac{1}{2} \ln |\Sigma_{22}| - \frac{1}{2} (\mathbf{y}_{2i} - \mathbf{x}_i \mathbf{\Pi}) \Sigma_{22}^{-1} (\mathbf{y}_{2i} - \mathbf{x}_i \mathbf{\Pi})'$$

and

$$m_i = (1 - \Sigma'_{21} \Sigma_{22}^{-1} \Sigma_{21})^{-\frac{1}{2}} \{ \mathbf{z}_i \boldsymbol{\delta} + (\mathbf{y}_{2i} - \mathbf{x}_i \mathbf{\Pi}) \Sigma_{22}^{-1} \Sigma_{21} \}$$

With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] **\_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*.

The maximum likelihood version of `ivprobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **Variance estimation**.

The two-step estimates are obtained using Newey's (1987) minimum  $\chi^2$  estimator. The reduced-form equation for  $y_{1i}^*$  is

$$\begin{aligned} y_{1i}^* &= (\mathbf{x}_i \mathbf{\Pi} + \mathbf{v}_i) \boldsymbol{\beta} + \mathbf{x}_{1i} \boldsymbol{\gamma} + u_i \\ &= \mathbf{x}_i \boldsymbol{\alpha} + \mathbf{v}_i \boldsymbol{\beta} + u_i \\ &= \mathbf{x}_i \boldsymbol{\alpha} + \nu_i \end{aligned}$$

where  $\nu_i = \mathbf{v}_i \boldsymbol{\beta} + u_i$ . Because  $u_i$  and  $\mathbf{v}_i$  are jointly normal,  $\nu_i$  is also normal. Note that

$$\boldsymbol{\alpha} = \begin{bmatrix} \mathbf{\Pi}_1 \\ \mathbf{\Pi}_2 \end{bmatrix} \boldsymbol{\beta} + \begin{bmatrix} \mathbf{I} \\ \mathbf{0} \end{bmatrix} \boldsymbol{\gamma} = D(\mathbf{\Pi}) \boldsymbol{\delta}$$

where  $D(\mathbf{\Pi}) = (\mathbf{\Pi}, \mathbf{I}_1)$  and  $\mathbf{I}_1$  is defined such that  $\mathbf{x}_i \mathbf{I}_1 = \mathbf{x}_{1i}$ . Letting  $\widehat{\mathbf{z}}_i = (\mathbf{x}_i \widehat{\mathbf{\Pi}}, \mathbf{x}_{1i})$ ,  $\widehat{\mathbf{z}}_i \boldsymbol{\delta} = \mathbf{x}_i D(\widehat{\mathbf{\Pi}}) \boldsymbol{\delta}$ , where  $D(\widehat{\mathbf{\Pi}}) = (\widehat{\mathbf{\Pi}}, \mathbf{I}_1)$ . Thus, one estimator of  $\boldsymbol{\alpha}$  is  $D(\widehat{\mathbf{\Pi}}) \boldsymbol{\delta}$ ; denote this estimator by  $\widehat{D} \boldsymbol{\delta}$ .

$\boldsymbol{\alpha}$  could also be estimated directly as the solution to

$$\max_{\boldsymbol{\alpha}, \boldsymbol{\lambda}} \sum_{i=1}^N l(y_{1i}, \mathbf{x}_i \boldsymbol{\alpha} + \widehat{\mathbf{v}}_i \boldsymbol{\lambda}) \quad (3)$$

where  $l(\cdot)$  is the log likelihood for probit. Denote this estimator by  $\widetilde{\boldsymbol{\alpha}}$ . The inclusion of the  $\widehat{\mathbf{v}}_i \boldsymbol{\lambda}$  term follows because the multivariate normality of  $(u_i, \mathbf{v}_i)$  implies that, conditional on  $\mathbf{y}_{2i}$ , the expected value of  $u_i$  is nonzero. Because  $\mathbf{v}_i$  is unobservable, the least-squares residuals from fitting (2) are used.

Amemiya (1978) shows that the estimator of  $\boldsymbol{\delta}$  defined by

$$\max_{\boldsymbol{\delta}} (\widetilde{\boldsymbol{\alpha}} - \widehat{D} \boldsymbol{\delta})' \widehat{\boldsymbol{\Omega}}^{-1} (\widetilde{\boldsymbol{\alpha}} - \widehat{D} \boldsymbol{\delta})$$

where  $\widehat{\boldsymbol{\Omega}}$  is a consistent estimator of the covariance of  $\sqrt{N}(\widetilde{\boldsymbol{\alpha}} - \widehat{D} \boldsymbol{\delta})$ , is asymptotically efficient relative to all other estimators that minimize the distance between  $\widetilde{\boldsymbol{\alpha}}$  and  $D(\widehat{\mathbf{\Pi}}) \boldsymbol{\delta}$ . Thus, an efficient estimator of  $\boldsymbol{\delta}$  is

$$\widehat{\boldsymbol{\delta}} = (\widehat{D}' \widehat{\boldsymbol{\Omega}}^{-1} \widehat{D})^{-1} \widehat{D}' \widehat{\boldsymbol{\Omega}}^{-1} \widetilde{\boldsymbol{\alpha}} \quad (4)$$

and

$$\text{Var}(\widehat{\boldsymbol{\delta}}) = (\widehat{D}' \widehat{\boldsymbol{\Omega}}^{-1} \widehat{D})^{-1} \quad (5)$$

To implement this estimator, we need  $\widehat{\boldsymbol{\Omega}}^{-1}$ .

Consider the two-step maximum likelihood estimator that results from first fitting (2) by OLS and computing the residuals  $\widehat{v}_i = y_{2i} - x_i \widehat{\Pi}$ . The estimator is then obtained by solving

$$\max_{\delta, \lambda} \sum_{i=1}^N l(y_{1i}, z_i \delta + \widehat{v}_i \lambda)$$

This is the two-step instrumental-variables (2SIV) estimator proposed by Rivers and Vuong (1988), and its role will become apparent shortly.

From Proposition 5 of Newey (1987),  $\sqrt{N}(\widetilde{\alpha} - \widehat{D}\delta) \xrightarrow{d} N(\mathbf{0}, \Omega)$ , where

$$\Omega = J_{\alpha\alpha}^{-1} + (\lambda - \beta)' \Sigma_{22} (\lambda - \beta) Q^{-1}$$

and  $\Sigma_{22} = E\{v_i' v_i\}$ .  $J_{\alpha\alpha}^{-1}$  is simply the covariance matrix of  $\widetilde{\alpha}$ , ignoring that  $\widehat{\Pi}$  is an estimated parameter matrix. Moreover, Newey shows that the covariance matrix from an OLS regression of  $y_{2i}(\widehat{\lambda} - \widehat{\beta})$  on  $x_i$  is a consistent estimator of the second term.  $\widehat{\lambda}$  can be obtained from solving (3), and the 2SIV estimator yields a consistent estimate,  $\widehat{\beta}$ .

Mechanically, estimation proceeds in several steps.

1. Each of the endogenous right-hand-side variables is regressed on all the exogenous variables, and the fitted values and residuals are calculated. The matrix  $\widehat{D} = D(\widehat{\Pi})$  is assembled from the estimated coefficients.
2. probit is used to solve (3) and obtain  $\widetilde{\alpha}$  and  $\widehat{\lambda}$ . The portion of the covariance matrix corresponding to  $\alpha$ ,  $J_{\alpha\alpha}^{-1}$ , is also saved.
3. The 2SIV estimator is evaluated, and the parameters  $\widehat{\beta}$  corresponding to  $y_{2i}$  are collected.
4.  $y_{2i}(\widehat{\lambda} - \widehat{\beta})$  is regressed on  $x_i$ . The covariance matrix of the parameters from this regression is added to  $J_{\alpha\alpha}^{-1}$ , yielding  $\widehat{\Omega}$ .
5. Evaluating (4) and (5) yields the estimates  $\widehat{\delta}$  and  $\text{Var}(\widehat{\delta})$ .
6. A Wald test of the null hypothesis  $H_0 : \lambda = \mathbf{0}$ , using the 2SIV estimates, serves as our test of exogeneity.

The two-step estimates are not directly comparable with those obtained from the maximum likelihood estimator or from probit. The argument is the same for Newey's efficient estimator as for Rivers and Vuong's (1988) 2SIV estimator, so we consider the simpler 2SIV estimator. From the properties of the normal distribution,

$$E(u_i | v_i) = v_i \Sigma_{22}^{-1} \Sigma_{21} \quad \text{and} \quad \text{Var}(u_i | v_i) = 1 - \Sigma_{21}' \Sigma_{22}^{-1} \Sigma_{21}$$

We write  $u_i$  as  $u_i = v_i \Sigma_{22}^{-1} \Sigma_{21} + e_i = v_i \lambda + e_i$ , where  $e_i \sim N(0, 1 - \rho^2)$ ,  $\rho^2 = \Sigma_{21}' \Sigma_{22}^{-1} \Sigma_{21}$ , and  $e_i$  is independent of  $v_i$ . In the second stage of 2SIV, we use a probit regression to estimate the parameters of

$$y_{1i} = z_i \delta + v_i \lambda + e_i$$

Because  $v_i$  is unobservable, we use the sample residuals from the first-stage regressions.

$$\Pr(y_{1i} = 1 | z_i, v_i) = \Pr(z_i \delta + v_i \lambda + e_i > 0 | z_i, v_i) = \Phi \left\{ (1 - \rho^2)^{-\frac{1}{2}} (z_i \delta + v_i \lambda) \right\}$$

Hence, as mentioned previously, 2SIV and Newey's estimator do not estimate  $\delta$  and  $\lambda$  but rather

$$\delta_\rho = \frac{1}{(1 - \rho^2)^{\frac{1}{2}}} \delta \quad \text{and} \quad \lambda_\rho = \frac{1}{(1 - \rho^2)^{\frac{1}{2}}} \lambda$$

## Acknowledgments

The two-step estimator is based on the `probitiv` command written by Jonah Gelbach of the University of California at Berkeley Law School and the `ivprob` command written by Joe Harkness of the University of Connecticut.

## Postestimation commands

The following postestimation commands are of special interest after `ivprobit`:

| Command                           | Description                                                                                        |
|-----------------------------------|----------------------------------------------------------------------------------------------------|
| <code>estat classification</code> | report various summary statistics, including the classification table                              |
| <code>estat correlation</code>    | report the correlation matrix of the errors of the dependent variable and the endogenous variables |
| <code>estat covariance</code>     | report the covariance matrix of the errors of the dependent variable and the endogenous variables  |
| <code>lroc</code>                 | compute area under ROC curve and graph the curve                                                   |
| <code>lsens</code>                | graph sensitivity and specificity versus probability cutoff                                        |

These commands are not appropriate after the two-step estimator or the `svy` prefix.

The following standard postestimation commands are also available:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| * <code>estat ic</code>      | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| *† <code>forecast</code>     | dynamic forecasts and simulations                                                                                                       |
| † <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| *† <code>lrtest</code>       | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |

## predict

### Description for predict

`predict` creates a new variable containing predictions such as structural functions, linear predictions, standard errors, and probabilities.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

After ML

```
predict [type] newvar [if] [in] [, statistic asfmethod rules asif]
```

```
predict [type] { stub* | newvarlist } [if] [in], scores
```

After twostep

```
predict [type] newvar [if] [in] [, twostep_statistic]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                   |                                                      |
|-------------------|------------------------------------------------------|
| <code>xb</code>   | linear prediction excluding endogeneity; the default |
| <code>pr</code>   | probability of a positive outcome                    |
| <code>stdp</code> | standard error of the linear prediction              |

| <i>asfmethod</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                       |                                          |
|-----------------------|------------------------------------------|
| <code>asf</code>      | average structural function; the default |
| <code>fixedasf</code> | fixed average structural function        |

| <i>twostep_statistic</i> | Description |
|--------------------------|-------------|
|--------------------------|-------------|

Main

|                   |                                         |
|-------------------|-----------------------------------------|
| <code>xb</code>   | linear prediction; the default          |
| <code>stdp</code> | standard error of the linear prediction |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`xb`, the default, calculates the linear prediction.

`pr` calculates the probability of a positive outcome. Results depend on how the endogeneity complication is handled, which is determined by the `asf` or `fixedasf` option. `pr` is not available with the two-step estimator.

`stdp` calculates the standard error of the linear prediction.

`asf` and `fixedasf` determine how the average structural function (ASF) of the specified statistic is computed. These options are not allowed with `xb` or `stdp`.

`asf` is the default for the ML estimator when the `pr` statistic is specified. `asf` computes the ASF of the specified statistic. It is the statistic conditional on the errors of the endogenous variable equations. Put another way, it is the statistic accounting for the correlation of the endogenous covariates with the errors of the main equation. Derivatives and contrasts based on `asf` have a structural interpretation. See [margins](#) for computing derivatives and contrasts.

`fixedasf` calculates a fixed ASF. It is the specified statistic using only the coefficients and variables of the outcome equation. `fixedasf` does not condition on the errors of the endogenous variable equations. Contrasts between two fixed counterfactuals averaged over the whole sample have a potential-outcome interpretation. Intuitively, it is as if the values of the covariates were fixed at a value exogenously by fiat. See [margins](#) for computing derivatives and contrasts.

To be clear, derivatives and contrasts between two fixed counterfactuals using the default `asf` option also have a potential-outcome interpretation. And, unlike `fixedasf`, they retain that interpretation when computed over subpopulations for both linear and nonlinear models.

`rules` requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations. `rules` is not available with the two-step estimator.

`asif` requests that Stata ignore the rules and the exclusion criteria and calculate predictions for all observations possible using the estimated parameters from the model. `asif` is not available with the two-step estimator.

`scores`, not available with `twostep`, calculates equation-level score variables.

For models with one endogenous regressor, four new variables are created.

The first new variable will contain  $\partial \ln L / \partial (z_i \delta)$ .

The second new variable will contain  $\partial \ln L / \partial (x_i \Pi)$ .

The third new variable will contain  $\partial \ln L / \partial \operatorname{atanh} \rho$ .

The fourth new variable will contain  $\partial \ln L / \partial \ln \sigma$ .

For models with  $p$  endogenous regressors,  $p + \{(p + 1)(p + 2)\}/2$  new variables are created.

The first new variable will contain  $\partial \ln L / \partial (z_i \delta)$ .

The second through  $(p + 1)$ th new score variables will contain  $\partial \ln L / \partial (x_i \Pi_k)$ ,  $k = 1, \dots, p$ , where  $\Pi_k$  is the  $k$ th column of  $\Pi$ .

The remaining score variables will contain the partial derivatives of  $\ln L$  with respect to  $s_{21}, s_{31}, \dots, s_{p+1,1}, s_{22}, \dots, s_{p+1,2}, \dots, s_{p+1,p+1}$ , where  $s_{m,n}$  denotes the  $(m, n)$  element of the Cholesky decomposition of the error covariance matrix.

## margins

### Description for margins

`margins` estimates margins of response for linear predictions and probabilities.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

#### After ML

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

##### Main

|                   |                                                      |
|-------------------|------------------------------------------------------|
| <code>xb</code>   | linear prediction excluding endogeneity; the default |
| <code>pr</code>   | probability of a positive outcome                    |
| <code>stdp</code> | not allowed with margins                             |

#### After twostep

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

##### Main

|                   |                                |
|-------------------|--------------------------------|
| <code>xb</code>   | linear prediction; the default |
| <code>stdp</code> | not allowed with margins       |

Statistics not allowed with margins are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## estat

### Description for estat

`estat correlation` displays the correlation matrix of the errors of the dependent variable and the endogenous variables.

`estat covariance` displays the covariance matrix of the errors of the dependent variable and the endogenous variables.

`estat correlation` and `estat covariance` are not allowed after the `ivprobit` two-step estimator.

### Menu for estat

Statistics > Postestimation

### Syntax for estat

*Correlation matrix*

```
estat correlation [, border(bspec) left(#) format(%fmt)]
```

*Covariance matrix*

```
estat covariance [, border(bspec) left(#) format(%fmt)]
```

### Options for estat

Main

`border`(*bspec*) sets border style of the matrix display. The default is `border(a11)`.

`left`(#) sets the left indent of the matrix display. The default is `left(2)`.

`format`(%*fmt*) specifies the format for displaying the individual elements of the matrix. The default is `format(%9.0g)`.

## Remarks and examples

Remarks are presented under the following headings:

*Marginal effects*

*Obtaining predicted values*

### Marginal effects

Below, we discuss the interpretation of the predicted probability,  $\text{pr}$ , with the `asf` and `fixedasf` options for the ML estimator using `margins`.

The model is defined by two equations. The first is the equation for the outcome of interest, given by

$$y_{1i}^* = \mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i$$

where we do not observe  $y_{1i}^*$ ; instead, we observe

$$y_{1i} = \begin{cases} 0 & y_{1i}^* < 0 \\ 1 & y_{1i}^* \geq 0 \end{cases}$$

The second is the equation for the endogenous covariates,  $\mathbf{y}_{2i}$ ,

$$\mathbf{y}_{2i} = \mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2 + \mathbf{v}_i$$

This last equation is the difference between a standard probit model and the model fit by `ivprobit`.  $\mathbf{y}_{2i}$  is modeled as an exogenous component,  $\mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2$ , and a component that is correlated with  $u_i$  and causes the endogeneity problem,  $\mathbf{v}_i$ . The ASF predicted probability conditions on an estimate of  $\hat{\mathbf{v}}_i$ . It is given by

$$\begin{aligned} \Phi(\hat{m}_i) &= \hat{P}(y_{1i} | \mathbf{x}_{1i}, \mathbf{x}_{2i}, y_{2i}, \hat{\mathbf{v}}_i) \\ \hat{m}_i &= \mathbf{y}_{2i}\hat{\boldsymbol{\theta}}_1 + \mathbf{x}_{1i}\hat{\boldsymbol{\theta}}_2 + \hat{\mathbf{v}}_i\hat{\boldsymbol{\theta}}_3 \end{aligned}$$

Because the correlation between  $\mathbf{v}_i$  and  $u_i$  is the problem we intended to address, conditioning on  $\mathbf{v}_i$  purges the model of endogeneity. Using the ASF, we can get derivatives and contrast. See [Wooldridge \(2010\)](#) and [Blundell and Powell \(2003\)](#) for an in-depth discussion of ASFs and their interpretation.

The fixed ASF, estimated when the `fixedasf` option is specified, has a different interpretation. Suppose we wanted to analyze  $1(\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i > 0)$  at two different values of  $\mathbf{y}_2$ , the original  $\mathbf{y}_2$  and  $\mathbf{y}_2 + 1$ .  $1(\cdot)$  is an indicator function that evaluates to 1 if the condition in parentheses is satisfied and 0 otherwise. We want the average difference at these two points for the given values of the other covariates. The values of the covariates are not arrived at via the model; they are fixed by fiat. You can think of them as potential outcomes. The difference of the two values of  $\mathbf{y}_2$  is given by

$$1\{(\mathbf{y}_{2i} + 1)\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i > 0\} - 1(\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i > 0)$$

If we average over the distribution of  $u$ , we obtain

$$\Phi\{(\mathbf{y}_{2i} + 1)\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma}\} - \Phi(\mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma})$$

We do not account for endogeneity because the values of the covariates are given and fixed. If the research question you are pursuing after fitting the model has this interpretation, `fixedasf` gives you an adequate prediction. If, however, you do not want to treat the covariates as fixed, you should account for endogeneity and use `asf` predictions.

### ▷ Example 1

We can obtain marginal effects by using the `margins` command after `ivprobit`. Continuing with [example 1](#) in [\[R\] ivprobit](#), we calculate the difference in the probability of a woman working, `fem_work`, if `other_inc` increases by 10% versus the probability when `other_inc` is unchanged. The effect we get has an ASF interpretation. The probabilities are estimated conditional on the residual from the endogenous variable. In other words, the computed effects condition on the level of endogeneity in the model. See [Wooldridge \(2010\)](#) for a discussion about the interpretation of the estimates and the computation of marginal effects of probit estimators under endogeneity.

```
. use https://www.stata-press.com/data/r19/laborsup
. ivprobit fem_work fem_educ kids (other_inc = male_educ)
 (output omitted)
. margins, at(other_inc = generate(other_inc))
> at(other_inc = generate(other_inc*1.10))
> contrast(at(r) nowald) predict(pr)

Contrasts of predictive margins Number of obs = 500
Model VCE: OIM

Expression: Average structural function probabilities, predict(pr)
1. _at: other_inc = other_inc
2. _at: other_inc = other_inc*1.10
```

|                 | Delta-method |           |           | [95% conf. interval] |
|-----------------|--------------|-----------|-----------|----------------------|
|                 | Contrast     | std. err. |           |                      |
| _at<br>(2 vs 1) | -.0762151    | .0100472  | -.0959073 | -.0565229            |

Here we see that a 10% increase in `other_inc` leads to an average decrease of 0.076 in the probability of `fem_work`. The effect we get has an ASF interpretation. The probabilities are estimated conditional on the residual from the endogenous variable. In other words, the computed effects condition on the level of endogeneity in the model. See [Wooldridge \(2010\)](#) for a discussion about the interpretation of the estimates and the computation of marginal effects of probit estimators under endogeneity.

## Obtaining predicted values

After fitting your model with `ivprobit`, you can obtain the linear prediction and its standard error for both the estimation sample and other samples by using the `predict` command; see [U] 20 Estimation and postestimation commands and [R] `predict`. If you use the maximum likelihood estimator, you can also obtain the predicted probability or the linear prediction with an ASF or fixed ASF interpretation.

`predict`'s `pr` option calculates the probability of a positive outcome, remembering any rules used to identify the model, and calculates missing for excluded observations. `predict`'s `rules` option uses the rules in predicting probabilities, whereas `predict`'s `asif` option ignores both the rules and the exclusion criteria and calculates probabilities for all possible observations by using the estimated parameters from the model. See *Obtaining predicted values* in [R] `probit postestimation` for an example.

## Stored results

`estat correlation` stores the following results in `r()`:

Matrices

`r(corr)` correlation matrix of the errors

`estat covariance` stores the following results in `r()`:

Matrices

`r(cov)` covariance matrix of the errors

## Methods and formulas

The linear prediction is calculated as  $z_i \hat{\delta}$ , where  $\hat{\delta}$  is the estimated value of  $\delta$ , and  $z_i$  and  $\delta$  are defined in (1a) of [R] `ivprobit`. The probability of a positive outcome is evaluated at  $m_i$ ,  $\Phi(m_i)$ , where  $\Phi(\cdot)$  is the standard normal distribution function and  $m_i$  is defined in *Methods and formulas* of [R] `ivprobit`. The ASF uses  $\hat{m}_i$  instead of  $y_{2i} \hat{\beta} + x_{1i} \hat{\gamma}$  to evaluate  $\Phi(\cdot)$  and account for endogeneity in the model. The fixed ASF is evaluated at  $y_{2i} \hat{\beta} + x_{1i} \hat{\gamma}$ .

## Description

`ivqregress` fits a linear instrumental-variables quantile regression (IVQR) model that accounts for endogenous covariates using two estimators: the inverse quantile regression (IQR) estimator proposed in [Chernozhukov and Hansen \(2006\)](#) and the smoothed estimating equations (SEE) estimator outlined in [Kaplan and Sun \(2017\)](#).

## Quick start

Use the IQR estimator to fit the median IVQR model of  $y_1$  on exogenous  $x_1$  and endogenous  $y_2$  with instruments  $z_1$  and  $z_2$

```
ivqregress iqr y1 x1 (y2 = z1 z2)
```

Same as above, but estimate the 0.75 quantile

```
ivqregress iqr y1 x1 (y2 = z1 z2), quantile(0.75)
```

Same as above, but estimate the 0.1, 0.2, ..., 0.9 quantiles

```
ivqregress iqr y1 x1 (y2 = z1 z2), quantile(10(10)90)
```

Use the SEE estimator to estimate the 0.6 quantile regression of  $y_1$  on exogenous  $x_1$  and endogenous  $y_2$  and  $y_3$  with instruments  $z_1$  and  $z_2$

```
ivqregress smooth y1 x1 (y2 y3 = z1 z2), quantile(0.6)
```

Same as above, but estimate the 0.1, 0.2, ..., 0.9 quantiles

```
ivqregress smooth y1 x1 (y2 y3 = z1 z2), quantile(10(10)90)
```

### *IQR options to control optimization*

Use 50 grid points in the IQR estimator to fit the 0.5 and 0.75 IVQR model

```
ivqregress iqr y1 x1 (y2 = z1 z2), ngrid(50) quantile(50 75)
```

Same as above, but construct grid points between 1 and 5 for all the quantiles

```
ivqregress iqr y1 x1 (y2 = z1 z2), ngrid(50) quantile(50 75) bound(1 5)
```

Same as above, but construct grid points using different bounds for different quantiles

```
ivqregress iqr y1 x1 (y2 = z1 z2), ngrid(50) quantile(50 75) ///
bound(1 5, at(50)) bound(2 6, at(75))
```

*SEE options to control optimization*

Use 2 as the initial bandwidth in the SEE estimator to fit the 0.5 and 0.75 IVQR model

```
ivregress smooth y x1 (d1 d2 = z1 z2), quantile(50 75) ///
 initbwidth(2)
```

Same as above, but use different initial bandwidths for different quantiles

```
ivregress smooth y x1 (d1 d2 = z1 z2), quantile(50 75) ///
 initbwidth(2, at(50)) initbwidth(1, at(75))
```

## Menu

Statistics > Endogenous covariates > Quantile regression with endogenous covariates

## Syntax

*Inverse quantile regression (IQR) estimator*

```
ivregress iqr depvar [varlist1] (varname = varlistiv) [if] [in] [, options
 IQR_options]
```

*Smoothed estimating equations (SEE) estimator*

```
ivregress smooth depvar [varlist1] (varlist2 = varlistiv) [if] [in] [, options
 SEE_options]
```

*varlist*<sub>1</sub> is the list of exogenous variables.

*varname* is an endogenous variable.

*varlist*<sub>2</sub> is the list of endogenous variables.

*varlist*<sub>iv</sub> is the list of exogenous variables used with *varlist*<sub>1</sub> as instruments for *varlist*<sub>2</sub> and *varname*.

*varlist*<sub>1</sub>, *varname*, *varlist*<sub>2</sub>, and *varlist*<sub>iv</sub> may contain factor variables; see [U] 11.4.3 Factor variables.

*bootstrap*, *by*, *collect*, *rolling*, and *statsby* are allowed; see [U] 11.1.10 Prefix commands.

*coeflegend* does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

*quantile*(*numlist*) specifies the quantiles to be estimated and should contain numbers between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default is *quantile*(0.5), which corresponds to the median.

### Options

The following options apply only to the IQR estimator.

*bound*(*#*<sub>min</sub> *#*<sub>max</sub> [ , *at*(*#*<sub>q</sub>) ]) specifies the lower bound (*#*<sub>min</sub>) and the upper bound (*#*<sub>max</sub>) for the grid in the *#*<sub>q</sub>th quantile estimation. By default, the bounds are determined by the two-stage quantile regression, extending the two-stage median regression in Amemiya (1982). This option is repeatable as long as different quantiles *#*<sub>q</sub> are given in each specification.

The specified bound is required to be wider than the *#*<sub>level</sub> confidence interval (CI) that is robust to the weak instruments, which is also known as dual CI. The value of *#*<sub>level</sub> can be specified in the *level*() option; the default is 95% CI.

The grid points are *#*<sub>g</sub> equally spaced points between *#*<sub>min</sub> and *#*<sub>max</sub>, where *#*<sub>g</sub> is specified by the *ngrid*() option.

*ngrid*(*#*<sub>g</sub>) specifies the number of grid points in the IQR estimator. The default is *ngrid*(30); that is, 30 grid points are used.

The following options apply only to the SEE estimator.

`initbwidth(#b [ , at(#q )])` specifies initial bandwidth #<sub>b</sub> to smooth the estimating equations for the #<sub>q</sub>th quantile estimation. The default is the theoretical optimal bandwidth that minimizes the mean squared errors of the estimating equations; see [Kaplan and Sun \(2017\)](#). This option is repeatable as long as different quantiles #<sub>q</sub> are given in each specification.

`iterate(#)` specifies the maximum number of iterations to perform when solving the estimating equation; the default is `iterate(100)`.

`nosearchbwidth` specifies to not search for a feasible bandwidth if the initial bandwidth is not estimable; the default is to search for a feasible bandwidth.

`tolerance(#)` specifies the tolerance used to determine whether successive estimates of the solution have converged. The default is `tolerance(1e-9)`.

`ztolerance(#)` specifies the tolerance used to determine whether the proposed solution to a zero-finding problem is sufficiently close to 0; the default is `ztolerance(1e-9)`.

---

#### SE/Robust

`vce([vcetype] [ , vceopts])` specifies the type of VCE to compute and the density estimation method to use in computing the VCE.

`vcetype` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`) and that use bootstrap methods (`bootstrap`); see [\[R\] vce\\_option](#).

`vceopts` available with `vcetype robust` are the following:

`kernel(kernel)` specifies the kernel method to be used by the nonparametric density estimator. The available kernel functions are `epanechnikov`, `epan2`, `biweight`, `cosine`, `gaussian`, `parzen`, `rectangle`, and `triangle`. The default is `epanechnikov`. See [\[R\] kdensity](#) for the kernel function forms.

`bwidth(#|bwrule)` specifies the bandwidth to be used by the nonparametric density estimator. If specified as a number, it is used as the bandwidth for the nonparametric density estimator. Otherwise, `bwrule` specifies the method used to compute the bandwidth. Available methods are `silverman` for Silverman's rule of thumb, `hsheather` for the Hall–Sheather bandwidth, and `bofinger` for the Bofinger bandwidth.

See [\[R\] kdensity](#) for Silverman's rule of thumb. See [Koenker \(2005, sec. 4.10\)](#) for a description of the Hall–Sheather and Bofinger bandwidth formulas.

---

#### Reporting

`level(#)`; see [\[R\] Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [\[R\] Estimation options](#).

## Optimization

`log` and `nolog` specify whether to display the log showing the progress of the estimation. By default, for the IQR estimator, one dot is shown for each grid point; for the SEE estimator, one line is shown for each bandwidth. The iteration log is displayed by default unless you used `set iterlog off` to suppress it; see `set iterlog` in [R] [set iter](#).

`verbose` displays a verbose log showing the iterations of each computation step. For the IQR estimator, each line is shown for each grid point. For the SEE estimator, iteration logs are shown when solving the estimating equations.

The following option is available with `ivqregress` but is not shown in the dialog box: `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

[Overview](#)

[When quantile regression matters](#)

[Examples](#)

## Overview

`ivqregress` fits a linear IVQR model when some covariates are endogenous. The general IVQR model was first proposed by [Chernozhukov and Hansen \(2005\)](#). `ivqregress` is based on the linear IVQR model described in [Chernozhukov and Hansen \(2006, 2008\)](#). For an introduction to the IVQR model, see [Chernozhukov, Hansen, and Wüthrich \(2018\)](#). `ivqregress` implements two estimators: the IQR estimator proposed in [Chernozhukov and Hansen \(2006\)](#) and the SEE estimator outlined in [Kaplan and Sun \(2017\)](#).

In empirical applications, we are usually interested in the effects of some covariate on the outcome variable. The traditional linear regression model is an excellent way to model how the covariate affects the outcome's conditional mean. However, sometimes we would like to study features of the outcome distribution other than the mean to have a complete picture of the effects of covariates. For example, a policymaker may want to learn how participation in a 401(k) would affect the lower-level, median, and upper-level conditional quantiles of net wealth.

Quantile regression in [Koenker and Bassett \(1978\)](#) can help us grasp a better picture than regular linear regression by estimating the effects on different quantiles of the outcome's conditional distribution. For a general discussion, see [R] [qreg](#). For an illustration of when quantile regression matters, see [When quantile regression matters](#) below.

In practice, some covariates of interest are often endogenous for reasons such as self-selection, omission of some relevant variable, and measurement error. For example, participation in a voluntary savings plan for retirement, such as participation in a 401(k) program, may be endogenous because the people who do and do not participate may have different saving preferences, which will affect net wealth growth.

Endogenous covariates make quantile regression estimates inconsistent, as is the case for the linear regression model. Analogous to the instrumental-variable least-squares estimator, there are IVQR model estimators to consistently estimate the effects at different quantiles. For a discussion of instrumental-variables estimation, see [R] [ivregress](#).

`ivqregress` fits a quantile regression model that accounts for endogenous covariates using two estimators: the IQR estimator proposed in Chernozhukov and Hansen (2006) and the SEE estimator outlined in Kaplan and Sun (2017). Intuitively, `ivqregress` can be thought of as the `ivregress` version of `qreg`.

Here we outline the Stata commands to fit, visualize, infer, and diagnose the IVQR model. In particular, these Stata commands can be grouped into the following categories.

**Estimation:** `ivqregress iqr` fits the IVQR model by the IQR estimator proposed in Chernozhukov and Hansen (2006, 2008).

`ivqregress smooth` fits the IVQR model by the SEE estimator proposed in Kaplan and Sun (2017).

**Visualization:** `estat coefplot` allows us to visualize how one covariate's effects vary at different quantiles of the outcome.

**Inference:** `estat endogeffects` tests if

1. the endogenous variable does not affect the outcome variable,
2. the effects of the endogenous variable do not vary across estimated quantiles,
3. the effects of the endogenous variable are greater than zero across estimated quantiles, and
4. the variable is exogenous instead of endogenous.

`estat dualci` provides CIs that are robust to weak instruments for the effects of the endogenous variable. It is allowed only after `ivqregress iqr`.

**Diagnosis:** `estat waldplot` helps diagnose the convergence of the IQR estimator (`ivqregress iqr`). In particular, `estat waldplot` allows us to visualize the optimization process during the computation in `ivqregress iqr` and shows if the searching domain contains the true value of the parameter with a predefined probability level.

In addition, some other classical postestimation tools are also available; see [R] [ivqregress postestimation](#).

## When quantile regression matters

Here is an example illustrating the advantages of quantile regressions. Suppose we have a simple model  $E(y|x) = \beta_0 + x\beta_1$ , where  $y$  is the outcome variable and  $x$  is a covariate. For simplicity, we assume  $x$  can only take values in  $\{0, 1, 2, 3, 4, 5, 6\}$ . By definition,  $\beta_1$  fully characterizes the effects of increasing one unit of  $x$  on the conditional mean of outcome  $y$ ; that is,  $\beta_1 = E(y|x = a + 1) - E(y|x = a)$ . Now we consider two scenarios of the data-generating process.

1. The probability density function of the outcome conditional on  $x = a + 1$ ,  $f(y|x = a + 1)$ , is only location shifted relative to  $f(y|x = a)$ . In this case,  $\beta_1$  summarizes the effect of  $x$  not only on the conditional mean but also on each conditional quantile of  $y$ . This case is illustrated in the left panel of [figure 1](#).

2. The probability density function of the outcome conditional on  $x = a + 1$ ,  $f(y|x = a + 1)$ , is both location shifted and rescaled relative to  $f(y|x = a)$ . In this case,  $\beta_1$  summarizes the effect of  $x$  only on the conditional mean but not on conditional quantiles of  $y$ . This case is illustrated in the right panel of [figure 1](#).

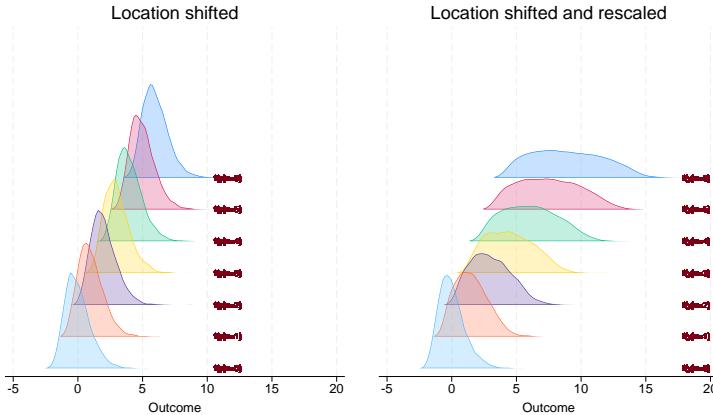

Figure 1.

In the left panel, we see that each conditional density is parallel relative to each other, and only the location has been shifted. In this case,  $\beta_1$  captures the shift in both conditional mean and any conditional quantiles of the outcome. As a result, running a linear regression provides as much information on  $\beta_1$  as quantile regression.

In contrast, in the right panel, conditional density for each level of  $x$  has different locations and different shapes. Thus,  $\beta_1$  can only summarize the shifts in conditional mean, which are generally different from the shifts in conditional quantiles. Quantile regression becomes necessary to learn about the effects of  $x$  on the conditional quantiles of the outcome.

## Examples

### ► Example 1: IVQR with the IQR estimator

Suppose that we want to estimate the effect of 401(k) participation (`p401k`) on different conditional quantiles of net financial assets (`assets`). We use data reported by [Chernozhukov and Hansen \(2004\)](#). These data are from a sample of households in the 1990 Survey of Income and Program Participation (SIPP). For the head of household, we have data on income (`income`), age (`age`), number of people in the family (`familysize`), years of education (`educ`), marital status (`married`), whether participated in an IRA (`ira`), whether received a pension benefit (`pension`), and whether owned a home (`ownhome`).

We suspect 401(k) participation is endogenous because it may depend on unobserved factors such as saving preference that also impact financial assets. Using 401(k) eligibility (`e401k`) as an instrument for 401(k) participation, we use `ivqregress` to estimate how `p401k` affects the entire range of `assets`' conditional distribution. One concern about using `e401k` as an instrument is that choosing to work for a company that offers a 401(k) program is not randomly assigned. [Poterba, Venti, and Wise \(1995\)](#) suggest that after conditioning on income, we can take working for a company that offers a 401(k) plan as exogenous.

The IVQR model we want to fit is

$$\text{assets}_i = \text{p401k}_i \alpha(U) + \text{covariates}'_i \beta(U)$$

where the distribution of  $U$  conditional on the instrument `e401k` and the covariates is assumed to be uniform between 0 and 1. The covariates `income`, `age`, `familysize`, and `educ` are included in the model as continuous variables. The covariates `i.married`, `i.ira`, `i.pension`, and `i.ownhome` are included as categorical (factor) variables. As discussed above, `e401k` is the instrument for `p401k`. The coefficients  $\alpha(U)$  and  $\beta(U)$  are random because they depend on the unobserved random variable  $U$ . In practice,  $U$  can be considered a ranking variable for the asset. When  $U$  is set to a fixed level  $\tau$ , we fit an IVQR model at a specific quantile index  $\tau$ . For example, when  $\tau = 0.5$ , we estimate how 401(k) participation affects the median of net financial assets conditional on other covariates.

The objective of the analysis is to estimate the quantile treatment effects of 401k participation on net financial assets. By definition, the  $\tau$ th conditional quantile of the asset when everyone participates in a 401(k) plan is

$$\text{assets}_{401(k)} = \alpha(\tau) + \text{covariates}'_i \beta(\tau)$$

In contrast, the  $\tau$ th conditional quantile of the asset when everyone does not participate in a 401(k) plan is

$$\text{assets}_{\text{no } 401(k)} = \text{covariates}'_i \beta(\tau)$$

Thus, the coefficient  $\alpha(\tau)$  can fully summarize the quantile treatment effect of `p401k` on `assets`. That is

$$\alpha(\tau) = \text{assets}_{401(k)} - \text{assets}_{\text{no } 401(k)}$$

In this example, we use the IQR estimator (`ivqregress iqr`) to estimate the effect of 401(k) participation on the conditional median of the net financial assets. The dependent variable is `assets`. The endogenous variable `i.p401k` and the instrument `i.e401k` are specified in parentheses; the other covariates follow as a regular variable list. `ivqregress` fits the IV median regression model by default. The estimation result is stored as `est_iqr` for later use.

| Yes         | -30.29657   | 154.7265            | -0.20 | 0.845 | -333.555             | 272.9618  |
| educ        | -96.43983   | 32.09465            | -3.00 | 0.003 | -159.3442            | -33.53547 |
| _cons       | -4998.673   | 570.1315            | -8.77 | 0.000 | -6116.11             | -3881.236 |

```

Endogenous: 1.p401k
Exogenous: income age familysize 1.married 1.ira 1.pension 1.ownhome educ
 1.e401k
. estimates store est_iqr

```

The coefficient for p401k is 5,313. It means participation in a 401(k) would increase the median net financial assets by \$5,313, conditional on other covariates, relative to a scenario where no one participates. We store the estimation result as `est_iqr` for later use.

After `ivqregress iqr`, we can use `estat dualci` to obtain the dual CI, which is robust to weak instruments, for the coefficient on the endogenous variable.

```

. estat dualci
Dual confidence interval Number of obs = 9,913

```

| assets | Coefficient | Robust<br>std. err. | z    | P> z  | Dual<br>[95% conf. interval] |          |
|--------|-------------|---------------------|------|-------|------------------------------|----------|
| p401k  |             |                     |      |       |                              |          |
| Yes    | 5313.397    | 573.2818            | 9.27 | 0.000 | 3683.916                     | 7304.986 |

The dual CI is usually wider than the regular CI, but it provides a more robust inference if the instruments are weak. In this example, we see that the dual 95% CI is [3684, 7305], which is wider than the regular 95% CI [4190, 6437].

### ▷ Example 2: IVQR with the smooth estimator

In this example, we use `ivqregress` to fit the IVQR model as in [example 1](#) but using the SEE estimator (`ivqregress smooth`). The model specification is the same as in [example 1](#). The estimation result is stored as `est_smooth` for later use.

```
. ivqregress smooth assets (i.p401k = i.e401k) income age familysize
> i.married i.ira i.pension i.ownhome educ
Fitting smoothed IV quantile regression:
Quantile = .5:
Step 1: Bandwidth = 1302.9736 GMM criterion Q(b) = 2.617e-08
Step 2: Bandwidth = 6079.6881 GMM criterion Q(b) = 2.391e-12
Step 3: Bandwidth = 1438.3068 GMM criterion Q(b) = 8.068e-13
IV median regression Number of obs = 9,913
Estimator: Smoothed estimating equations Wald chi2(9) = 1243.05
 Prob > chi2 = 0.0000
```

| assets      | Robust      |           |       |       | [95% conf. interval] |           |

| _cons       | -5672.645   | 619.7049  | -9.15 | 0.000 | -6887.244            | -4458.045 |

```
Endogenous: 1.p401k
Exogenous: income age familysize 1.married 1.ira 1.pension 1.ownhome educ
 1.e401k
. estimates store est_smooth
```

The interpretation of the coefficient estimates is the same as in [example 1](#). For example, the coefficient for `p401k` is 5,364. So participation in a 401(k) would increase the median of net financial assets by \$5,364, conditional on other covariates, relative to a scenario where no one participates.

Now we can compare the coefficient on p401k between the SEE estimator and the IQR estimator.

```
. estimates table est_iqr est_smooth, keep(i.p401k) se
```

| Variable | est_iqr   | est_smooth |

We see that the point estimates from these two estimators are similar but not the same. It is normal to see different results from the IQR and SEE estimators because these two estimators approximate the original exact estimating equation differently. On one hand, the IQR estimator tries to find the solution by an exhaustive grid search. The estimation result critically depends on the range and finesse of grid points. On the other hand, the SEE estimator uses a kernel method to smooth the original estimating equation. Its result depends on how well the SEE approximates the original, mainly controlled by the bandwidth.

Both the IQR and SEE estimators have their advantages and weaknesses. The IQR estimator is numerically stable, and it allows computing the dual CI, which is robust to weak instruments (use `estat dualci`). However, the IQR becomes computationally intensive when there is more than one endogenous variable. Thus, `ivqregress iqr` allows only one endogenous variable. In contrast, the SEE estimator can handle multiple endogenous variables within a reasonable computation time. However, it does not allow `estat dualci` for inference that is robust to weak instruments. Suppose there is only one endogenous variable in the model. We recommend using both estimators, comparing the results, and using the IQR estimator as a benchmark because it can provide valid inference even if the instrument is weak. If there is more than one endogenous variable, only `ivqregress smooth` is available.

◀

### ► Example 3: IVQR at different quantiles

In the first two examples, we estimated the 401(k) participation (p401k) treatment effect on the conditional median of net financial assets (`assets`). From a policy designer's point of view, we may be more interested in estimating the treatment effect of p401k on other conditional quantiles of assets. For example, we can ask questions like 1) how 401(k) participation affects the lower quantile of assets and 2) whether 401(k) participation is unambiguously beneficial for the asset's lower and upper conditional quantiles. In addition, we might also want to know whether the 401(k) participation is endogenous in our model. In this example, we will show how to use `ivqregress` to fit the IVQR model at different quantiles and how to use the postestimation tools to answer the above questions.

First, we use the IQR estimator to fit the model at different quantiles. In particular, we specify the `quantile(10(10)90)` option to fit the IVQR model at the 10th, 20th, ..., 90th quantiles.

```
. ivregress iqr assets (i.p401k = i.e401k) income age familysize
> i.married i.ira i.pension i.ownhome educ, quantile(10(10)90)

Endogenous: 1.p401k

Exogenous: income age familysize 1.married 1.ira 1.pension 1.ownhome educ  
1.e401k

The results show the estimates for the effect of 401(k) participation on each conditional quantile of the asset. The interpretation of the coefficient is similar to [example 1](#), except we are looking at different conditional quantiles. For example, for quantile q90, the estimate for the coefficient on p401k is 15,983. Thus, 401(k) participation would increase the 90% conditional quantile of net financial assets by \$15,983.

In addition to looking at the numerical estimates from the coefficient table, we can use `estat coefplot` to visualize the trend of p401k's treatment effect from the lower to the upper quantile. By default, `estat coefplot` shows the first endogenous variable, which is 1.p401k in our example. We specify the `name()` option for later reference of this graph and add a subtitle indicating which estimator we used.

```
. estat coefplot, name(cp_iqr) subtitle(IQR estimator)
```

The dots in the plot show the point estimates of p401k's treatment effect on different conditional quantiles of assets, and the gray bound shows the 95% pointwise CI. We see that there is an upward trend of p401k's treatment effect. At lower-level quantiles such as the 10th, 20th, ..., 40th quantiles, the treatment effect is relatively flat. However, we see the treatment effect increases significantly in the upper-level quantiles. The red line shows the two-stage least-squares estimates, which can be used as a benchmark.

`estat coefplot` is a good way to visualize the treatment effect's trend. If we want to test some hypotheses regarding the trend and the model statistically, we can use `estat endogeffects`. For example, we are interested in testing the following hypotheses:

- No effect:** 401(k) participation does not affect net financial assets for all the estimated quantiles.
- Constant effect:** 401(k) participation's treatment effect is constant for all the estimated quantiles.
- Dominance:** 401(k) participation is unambiguously positive for all the estimated quantiles; that is, the coefficient values are strictly positive.
- Exogeneity:** 401(k) participation is exogenous.

We will use `estat endogeffects` to show the Kolmogorov–Smirnov statistic and the 95% critical value for each hypothesis. We can reject the null hypothesis if the test statistic is greater than the critical value; otherwise, we cannot reject the null hypothesis. We specify the `rseed()` option to make the results reproducible because the critical values are generated from a bootstrap sample.

```
. estat endogeffects, rseed(12345671)

Tests for endogenous effects Replications = 100

Null hypothesis	KS statistic 95% critical value
No effect | 11.271 2.554
Constant effect | 5.395 2.446
Dominance | 0.000 2.467
Exogeneity | 4.145 2.478
-----|-----
```

Note: If the KS statistic < critical value, there is insufficient evidence to reject the null hypothesis. (KS = Kolmogorov-Smirnov)

In particular, we see that the test statistics are greater than the critical values in testing the hypotheses of no effect, constant effect, and exogeneity. Thus, with a 95% confidence level, we can reject these three hypotheses. In other words, we find that 401(k) participation has some effect, treatment is not constant across different quantiles, and 401(k) participation is endogenous. In contrast, we cannot reject the dominance hypothesis. Thus, we find that 401(k) participation is unambiguously beneficial for all the estimated quantiles of assets.

The test results are consistent with the result of the coefficient plot produced by `estat coefplot`, where we saw that the treatment effects are positive (dominance and no effect hypotheses) and upward trended (constant effect hypothesis).

For comparison, we can also use the SEE estimator to fit the model.

 1.e401k

After `ivqregress smooth`, we can also use `estat coefplot` to visualize the treatment effect and `estat endoeffects` to test some hypotheses of particular interest in the context of the IVQR model.

First, we use `estat coefplot` to plot the coefficients and then use `graph combine` so that we can visually compare this plot with the coefficients plot for the IQR estimates.

```
. estat coefplot, name(cp_smooth) subtitle(SEE estimator)
. graph combine cp_iqr cp_smooth, xcommon ycommon altshrink
```

The left and right panels of the figure show the coefficient plots for the IQR and SEE estimates, respectively. We see that both estimators produce similar trends for the coefficients on 1.p401k at different quantiles.

Next, we can use `estat endogeffects` to see if we draw the same conclusion regarding the four hypotheses of interest as we did with the IQR estimator.

```
. estat endogeffects, rseed(12345671)
Tests for endogenous effects Replications = 100
```

| Null hypothesis | KS statistic | 95% critical value |
|-----------------|--------------|--------------------|
| No effect       | 11.507       | 2.593              |
| Constant effect | 5.351        | 2.391              |
| Dominance       | 0.000        | 2.556              |
| Exogeneity      | 4.195        | 2.526              |

Note: If the KS statistic < critical value, there is insufficient evidence to reject the null hypothesis. (KS = Kolmogorov-Smirnov)

The results align with those produced after `ivqregress iqr`. That is, the treatment effects are positive (dominance and no effect hypotheses), upward trended (constant effect hypothesis), and endogenous (exogeneity hypothesis).

#### ► Example 4: Robustness checks and diagnostics for the IQR estimator

In this example, we will take a closer look at the IQR estimator and show how to use `estat waldplot` to inspect the convergence visually. Nevertheless, let's first briefly discuss the intuition and algorithm behind the IQR estimator.

The IVQR model satisfies the following conditional probability:

$$\Pr(y \leq d\alpha(\tau) + \mathbf{x}'\beta(\tau) | \mathbf{x}, \mathbf{z}) = \tau$$

where  $y$  is the outcome variable,  $d$  is an endogenous variable,  $\mathbf{x}$  is a vector of exogenous covariates, and  $\mathbf{z}$  is a vector of instruments. The coefficients  $\alpha(\tau)$  and  $\beta(\tau)$  are indexed with the quantile level  $\tau$  to indicate that they are for the model of the  $\tau$  conditional quantile of the outcome  $y$ . We cannot fit the above model using the regular quantile regression because the conditional set is on  $\mathbf{x}$  and  $\mathbf{z}$  but the covariates contain  $\mathbf{x}$  and  $d$ . Now suppose we know the value of  $\alpha(\tau)$ . We can then rewrite this conditional probability as

$$\Pr(y - d\alpha(\tau) \leq \mathbf{x}'\beta(\tau) + \mathbf{z}'\mathbf{0} | \mathbf{x}, \mathbf{z}) = \tau$$

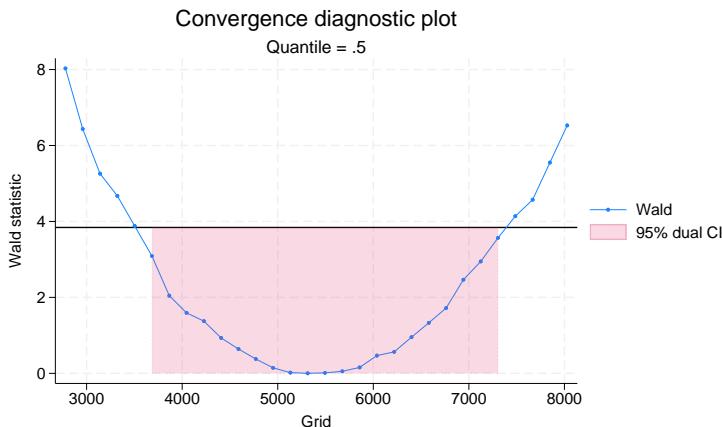

By the definition of quantile regression, we can fit this model by running a quantile regression of the transformed outcome variable,  $y - d\alpha(\tau)$ , on the covariates  $\mathbf{x}$  and instruments  $\mathbf{z}$ . Notice that if  $\alpha(\tau)$  is the true value, the coefficient on the instruments, which we denote as  $\gamma(\tau)$ , should be 0. In other words, to solve the original moment conditional for the IVQR model, we need to find a  $\alpha(\tau)$  such that the auxiliary quantile regression of  $y - d\alpha(\tau)$  on  $\mathbf{x}$  and  $\mathbf{z}$  produces 0s for the coefficients on the instrument  $\mathbf{z}$ . In practice, we want  $\gamma(\tau)$  as close to 0 as possible, where the closeness to 0 can be measured by the Wald statistic on  $\gamma(\tau)$ .

Based on the above intuition, here is an outline of the IQR estimator's algorithm.

1. Define a grid of  $A = \{\alpha_1, \dots, \alpha_J\}$  (see *IQR default grid algorithm* in *Methods and formulas*).
2. For each  $\alpha_j$  in  $A$ , run an auxiliary quantile regression of  $y - d\alpha_j$  on covariates  $\mathbf{x}$  and instruments  $\mathbf{z}$ .
3. IQR finds  $\alpha_k \in A$  as a solution such that the coefficient on  $\mathbf{z}$  is as close to 0 as possible in the corresponding auxiliary quantile regression, where the Wald statistic measures the closeness to 0.
4. The grid points boundary must be wider than the dual CI, which is robust to weak instruments; otherwise, `ivqregress iqr` will error out. Dual CI means it covers the true value of  $\alpha(\tau)$  with 95% probability (see [Chernozhukov and Hansen \[2008\]](#) and `estat dualci`).

We can use `estat waldplot` to visualize the above procedure. Using the estimation result in [example 1](#), we first restore the result `est_iqr` and then use `estat waldplot` to plot the Wald statistics corresponding to each grid point.

```
. estimates restore est_iqr
(results est_iqr are active now)
. estat waldplot
```

The horizontal axis shows the grid points for  $\alpha$ , and the vertical axis shows the values of the Wald statistics. The dots in the plot show the Wald statistics corresponding to each grid point. The red line is the 95% critical value of the Wald test. Thus, only the Wald statistics below the red line will not reject the hypothesis that  $\gamma_j$  equals 0. Respectively, the 95% dual CI corresponds to the  $\alpha$ 's for which the Wald statistics are below the critical value. See [example 1](#) for the use of `estat dualci` to show the numerical values of the dual CI.

By default, `ivqregress iqr` uses the dual CI to generate the lower and upper bounds for the grid points to make sure that the grid covers the true value of parameter  $\alpha$  with a large probability. Sometimes, we may want to customize the bounds. For example, suppose we want to search grid points between 3,000 and 6,000. We can use the `bound()` option for this purpose.

```
. ivqregress iqr assets (i.p401k = i.e401k) income age familysize
> i.married i.ira i.pension i.ownhome educ, bound(3000 6000)

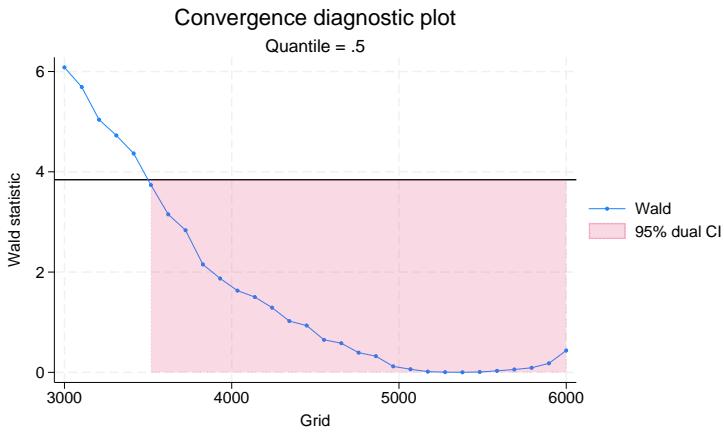

Initial grid:
Quantile = 0.50:10.....20.....30

convergence not achieved
The grid interval should be wider than the 95% dual confidence interval.
Try to set a wider bound using option bound(). Use estat waldplot for
diagnosis.
r(430);
```

We see that `ivqregress iqr` stops with a “convergence not achieved” error message. The reason is that the specified bound is too narrow to cover the true value of the parameter with a 95% probability.

We can now use `estat waldplot` to further visualize the issue.

```
. estat waldplot
```

The graph shows that the upper bound of 6,000 is too small because we need the Wald statistics to intersect with the 95% critical value at the lower and upper bounds.

We can increase the upper bound and see if the IQR estimator converges. For example, below we increase the upper bound to 8,000.

```
. ivqregress iqr assets (i.p401k = i.e401k) income age familysize
> i.married i.ira i.pension i.ownhome educ, bound(3000 8000)

Initial grid
quantile = 0.50:10.....20.....30

Adaptive grid
quantile = 0.50:10.....20.....30

IV median regression
Estimator: Inverse quantile regression

Number of obs = 9,913
Wald chi2(9) = 1290.41
Prob > chi2 = 0.0000
```

| r(table) | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Methods and formulas are presented under the following headings:

- The model*
- The IQR estimator*
- The IQR algorithm*
- The IQR default grid algorithm*
- The SEE estimator*
- The bandwidth selection algorithm*
- The robust standard errors*

## The model

The general IVQR model was first proposed by [Chernozhukov and Hansen \(2005\)](#). `ivqregress` fits a linear IVQR model described in [Chernozhukov and Hansen \(2006, 2008\)](#). For notational simplicity, we drop the observational subscript  $i$  to refer to a random variable and add the subscript  $i$  to refer to a realization of a random variable.

We can write the linear IVQR model in the form of a “random coefficients” model as

$$y = \mathbf{d}'\boldsymbol{\alpha}(u) + \mathbf{x}'\boldsymbol{\beta}(u)$$

where

- $y$  is a scalar outcome variable,  $\mathbf{d}$  is a vector of endogenous variables,  $\mathbf{x}$  is a vector of exogenous variables, and  $u$  is the unobserved error term;
- $\mathbf{d}$  depends on the exogenous covariates  $\mathbf{x}$ , and the instrumental variables  $\mathbf{z}$  and unobserved error term are correlated with  $u$ ;
- $u$  is a scalar random variable that characterizes the heterogeneity of the outcome and captures all the unobservables in the outcome from item 1 above. Conditional on  $\mathbf{z}$  and  $\mathbf{x}$ ,  $u$  is uniformly distributed between 0 and 1;
- $\boldsymbol{\alpha}(\cdot)$  and  $\boldsymbol{\beta}(\cdot)$  are random coefficient vectors that depend on  $u$ ;
- the function  $\tau \rightarrow \mathbf{d}'\boldsymbol{\alpha}(\tau) + \mathbf{x}'\boldsymbol{\beta}(\tau)$  is strictly increasing in  $\tau$ ; and
- the observable variables are  $\{y_i, \mathbf{x}_i, \mathbf{d}_i, \mathbf{z}_i\}_{i=1}^N$  with a sample of size  $N$ .

Under some regularity conditions (see Chernozhukov and Hansen [2005]), the IVQR model satisfies the conditional probability

$$\Pr\{y \leq \mathbf{d}'\boldsymbol{\alpha}(\tau) + \mathbf{x}'\boldsymbol{\beta}(\tau) | \mathbf{x}, \mathbf{z}\} = \tau \quad (1)$$

By the definition of probability and the law of iterated expectation, (1) implies the following unconditional moment condition:

$$E([\tau - I\{y \leq \mathbf{d}'\boldsymbol{\alpha}(\tau) + \mathbf{x}'\boldsymbol{\beta}(\tau)\}] \Psi) = 0 \quad (2)$$

where  $I(\cdot)$  is the indicator function,  $\Psi = (\hat{\mathbf{d}}', \mathbf{x}')$ , and  $\hat{\mathbf{d}}$  is some function of  $\mathbf{x}$  and  $\mathbf{z}$  and can be treated as instruments for  $\mathbf{d}$ . In practice,  $\hat{\mathbf{d}}$  is the linear prediction of  $\mathbf{d}$  using  $\mathbf{x}$  and  $\mathbf{z}$ .

Equation (2) can be used as the estimating equation for the IVQR model. However, the objective function based on (2) is nonconvex and nonsmooth because of the indicator function. Thus, it is computationally challenging to fit the IVQR model by directly using (2).

`ivqregress` implements two estimators that approximately solve the original moment condition in (2). In particular, `ivqregress iqr` implements the IQR estimator proposed in Chernozhukov and Hansen (2006), and `ivqregress smooth` implements the SEE estimator outlined in Kaplan and Sun (2017). Here are the main ideas behind these two estimators.

The IQR estimator reduces the original  $p$ -dimensional (where  $p$  is the dimension of  $\mathbf{x}$  and  $\mathbf{d}$ ) nonconvex problem into a low-dimensional nonconvex problem. Then, it solves the problem by doing an exhaustive grid search over a high-quality grid. The grid is high quality in the sense that it covers the true value of the parameter for  $\alpha(\tau)$  with a high probability (Chernozhukov and Hansen 2008). As a byproduct, the IQR estimator can also provide the CI that is robust to the weak instruments, which is also known as dual CI (see `estat dualci`). However, the IQR estimator becomes computationally intensive if there is more than one endogenous variable. As a result, `ivqregress iqr` allows only one endogenous variable.

The SEE estimator smooths the original moment condition in (2) using a kernel method to approximate the indicator function. Thus, the optimization problem reduces to solving a system of smooth nonlinear equations. One advantage of the SEE estimator compared with the IQR estimator is that it can handle more than one endogenous variable. However, it cannot provide the dual CI, which is robust to weak instruments like the IQR estimator.

While the IQR and SEE estimators are consistent for the IVQR model, their results are generally different. The reason is that the two estimators approximate the original moment condition in different ways. On one hand, the IQR estimator tries to find the solution by an exhaustive grid search. The estimation result critically depends on the range and finesse of grid points. On the other hand, the SEE estimator uses a kernel method to smooth the original estimating equation. Its result depends on how well the SEE estimator approximates the original, mainly controlled by the bandwidth.

In practice, suppose there is only one endogenous variable in the model. We recommend using both estimators, comparing the results, and using the IQR estimator as a benchmark because it can provide valid inference even if the instruments are weak.

## The IQR estimator

Before diving into the details, we discuss the intuition of the IQR estimator. The IVQR model satisfies the conditional probability

$$\Pr\{y \leq d\alpha(\tau) + \mathbf{x}'\boldsymbol{\beta}(\tau) | \mathbf{x}, \mathbf{z}\} = \tau$$

We cannot fit the above model using regular quantile regression because the conditional set is on  $\mathbf{x}$  and  $\mathbf{z}$ , but the covariates contain  $\mathbf{x}$  and  $d$ . Now suppose we know the value of  $\alpha(\tau)$ . We can then rewrite this conditional probability as

$$\Pr\{y - d\alpha(\tau) \leq \mathbf{x}'\beta(\tau) + \mathbf{z}' * 0 | \mathbf{x}, \mathbf{z}\} = \tau$$

By the definition of quantile regression, we can fit this model by running a quantile regression of the transformed outcome variable,  $y - d\alpha(\tau)$ , on the covariates  $\mathbf{x}$  and instruments  $\mathbf{z}$ . Notice that if  $\alpha(\tau)$  is the actual value, the coefficient on the instruments, which we denote as  $\gamma(\tau)$ , should be 0. In other words, to solve the original moment conditional for the IVQR model, we need to find a  $\alpha(\tau)$  such that the auxiliary quantile regression of  $y - d\alpha(\tau)$  on  $\mathbf{x}$  and  $\mathbf{z}$  produces zeros for the coefficients on the instruments  $\mathbf{z}$ . In practice, we want  $\gamma(\tau)$  as close to 0 as possible, where the closeness to 0 can be measured by the Wald statistic on  $\gamma(\tau)$ .

Based on the above intuition, here is an outline of the IQR estimator's algorithm.

### The IQR algorithm

1. Compute  $\hat{\mathbf{d}}$ , which is the linear projection of  $\mathbf{d}$  on  $\mathbf{x}$  and  $\mathbf{z}$ .  $\hat{\mathbf{d}}$  can be treated as instruments for  $\mathbf{d}$ .
2. Define a grid of  $A = \{\alpha_1, \dots, \alpha_J\}$ . For the algorithm of the default grid generation, see [The IQR default grid algorithm](#).
3. For each  $\alpha_j$  in  $A$ , run an auxiliary quantile regression of  $y - d\alpha_j$  on covariates  $\mathbf{x}$  and instruments  $\hat{\mathbf{d}}$ .
4. IQR finds  $\alpha_k \in A$  as a solution such that the coefficient on  $\hat{\mathbf{d}}$  is as close to 0 as possible in the corresponding auxiliary quantile regression, where the Wald statistic measures the closeness to 0.
5. The grid points boundary must be wider than the dual CI, which is robust to weak instruments; otherwise, `ivqregress iqr` will error out. Dual CI means it covers the true value of  $\alpha(\tau)$  with  $\#_{\text{level}}$  probability (see [Chernozhukov and Hansen \[2008\]](#) and `estat dualci`). The `level()` option specifies the confidence level  $\#_{\text{level}}$ ; the default is `level(95)`.

### The IQR default grid algorithm

The default grid algorithm can be divided into two stages: 1) the initial grid generation based on the two-stage quantile regression, which extends the two-stage median regression in [Amemiya \(1982\)](#); and 2) the adaptive grid that depends on the dual CI, which is robust to weak instruments ([Chernozhukov and Hansen 2008](#)).

1. Initial grid based on two-stage quantile regression
  - (a) Run a quantile regression of  $y$  on  $\mathbf{x}$  and  $\hat{\mathbf{d}}$ . Denote  $\tilde{\alpha}$  as the point estimate for the coefficient on  $\hat{\mathbf{d}}$  and  $\tilde{s}$  as its standard errors.  $\tilde{s}$  is computed by assuming the error term is normally distributed.
  - (b) Compute the lower and upper bounds of the grid. The lower bound is  $\text{lb} = \tilde{\alpha} - 4\tilde{s}$ , and the upper bound is  $\text{ub} = \tilde{\alpha} + 4\tilde{s}$ .
  - (c) By default, the grid points are  $\#_g$  equally spaced points between  $\text{lb}$  and  $\text{ub}$ , where the `ngrid()` option specifies the number of grid points  $\#_g$ .

## 2. Adaptive grid based on the dual CI

- (a) Given the initial grid, go through the steps 3–5 in *The IQR algorithm*.
- (b) Obtain the dual CI based on the initial grid.
- (c) Use the dual CI as the bound for the adaptive grid points and generate  $\#_g$  equally spaced points.

## The SEE estimator

The basic idea of the SEE estimator is to replace the indicator function in (2) with a smooth function. To be precise, we replace the moment condition in (2) with

$$E\left([\tau - \tilde{I}\{y - \mathbf{d}'\boldsymbol{\alpha}(\tau) - \mathbf{x}'\boldsymbol{\beta}(\tau) \leq 0\}] \Psi\right) = 0 \quad (3)$$

where  $\tilde{I}(v/h) = \max[0, \min\{1, (1 - v/h)/2\}]$  and  $h$  is the bandwidth. By default, the bandwidth is computed using the theoretical optimal bandwidth that minimizes the mean squared errors of the estimating equations. See proposition 2 in Kaplan and Sun (2017) for the optimal bandwidth.

Because  $\tilde{I}(\cdot)$  is a smooth function, the SEE estimator reduces to solve a system of smooth nonlinear equations. Let  $F(\theta)$  denote the left-hand side of (3), where  $\theta = \{\boldsymbol{\alpha}(\tau), \boldsymbol{\beta}(\tau)\}$ . Let  $\theta(i)$  denote the proposed solution at iteration  $i$ , and let  $\theta(i - 1)$  denote the proposed solution at the previous iteration. The convergence is declared if  $\text{mreldif}(\theta(i), \theta(i - 1)) < \text{itol}$  or  $F(\theta)'F(\theta) < \text{ztol}$ , where *itol* and *ztol* can be specified by using the `tolerance()` and `ztolerance()` options, respectively. The maximum number of iterations can be specified by using the `iterate()` option.

By default, the SEE estimator searches for the bandwidth as follows.

## The bandwidth selection algorithm

Denote  $\hat{\theta}_0$  as the initial values for the parameters  $\boldsymbol{\alpha}(\tau)$  and  $\boldsymbol{\beta}(\tau)$ . Denote  $\widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0)$  as the optimal bandwidths based on the initial values  $\hat{\theta}_0$ .  $\widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0)$  is a vector with elements  $(h_1, h_2, h_3)$ , where  $h_1$  is a nonparametrically estimated bandwidth,  $h_2$  assumes Gaussian distribution, and  $h_3$  uses the Silverman rule of thumb. Regardless of the assumption used, each element in  $\widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0)$  requires initial estimates of the error term  $\epsilon = y - \mathbf{d}'\boldsymbol{\alpha}(\tau) - \mathbf{x}'\boldsymbol{\beta}(\tau)$ . Thus, the optimal bandwidth is a function of the initial estimates for  $\boldsymbol{\alpha}(\tau)$  and  $\boldsymbol{\beta}(\tau)$ . For details, see section 5.4 in Kaplan (2022).

1. Let  $\hat{\theta}_0$  be the estimates of a quantile regression of  $y$  on  $\mathbf{d}$  and  $\mathbf{x}$ .
2. Based on  $\hat{\theta}_0$ , compute the optimal bandwidths  $\widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0)$ .
3. Define the initial bandwidth set as  $\mathbf{h}_0 = \{\widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0), h_{\text{init}}\}$ , where  $h_{\text{init}}$  is the bandwidth in the `initbwidth()` option if specified.  $\mathbf{h}_0 = \widehat{\mathbf{h}}_{\text{opt}}(\hat{\theta}_0)$  if `initbwidth()` is not specified.

4. Find the smallest element in  $\mathbf{h}_0$  such that it solves (3). The estimates for  $\alpha(\tau)$  are within the dual CI with  $\#_{\text{level}}$  probability (see Chernozhukov and Hansen [2008]).

- (a) If a valid bandwidth is found, go to step 5.
- (b) Otherwise, do a bisection search of the bandwidth with the upper bound as  $100 \times \min(\mathbf{h}_0)$  and the lower bound as  $\min(\mathbf{h}_0)/100$ .

If a valid bandwidth is found, denote it as  $h^*$ .

5. Update  $\hat{\theta}_0$  as the solution for the SEE estimator based on bandwidth  $h^*$ . Repeat steps 2–4 based on the updated  $\hat{\theta}_0$ .

By default, steps 1–5 are used to select the bandwidth. If the `nosearchbw` and `initbwidth()` options are both specified, steps 2, 4b, and 5 are omitted. Thus, in this case, `ivqregress smooth` will try to solve (3) with the specified initial bandwidth without searching for the optimal or feasible bandwidths. If only the `nosearchbw` option is specified, step 4b is omitted.

### The robust standard errors

The robust asymptotic variance–covariance estimator for the IQR and SEE estimators can be estimated as follows (see Chernozhukov and Hansen [2006] and de Castro et al. [2019]). Let  $\theta = \{\alpha(\tau), \beta(\tau)\}$  be the true values of parameters and  $\hat{\theta} = \{\widehat{\alpha(\tau)}, \widehat{\beta(\tau)}\}$  be the IQR or the SEE estimator. For any finite collection of quantile indices  $\tau_j, j \in T$

$$[\sqrt{n}\{\hat{\theta}(\tau) - \theta(\tau)\}]_{j \in T} \rightarrow N(0, [\mathbf{J}(\tau_k)^{-1} \mathbf{S}(\tau_j, \tau_k) \{\mathbf{J}(\tau_j)^{-1}\}']_{k, j \in T})$$

where

$$\begin{aligned} \mathbf{J}(\tau) &= E\{f_{\epsilon(\tau)}(0|\mathbf{x}, \mathbf{d}, \mathbf{z})\Psi[\mathbf{d}', \mathbf{x}']\} \\ \mathbf{S}(\tau_j, \tau_k) &= \{\min(\tau_j, \tau_k) - \tau_j\tau_k\}E(\Psi\Psi') \end{aligned}$$

and  $f_{\epsilon(\tau)}(0|\mathbf{x}, \mathbf{d}, \mathbf{z})$  is the conditional density of  $\epsilon(\tau)$  evaluated at 0, with  $\epsilon_i(\tau) = y_i - \mathbf{d}'_i\alpha(\tau) - \mathbf{x}'_i\beta(\tau)$ .

The components in the variance can be obtained by their sample counterparts. In particular,  $\mathbf{S}(\cdot)$  can be estimated as

$$\hat{\mathbf{S}}(\tau_k, \tau_j) = \{\min(\tau_k, \tau_j) - \tau_k\tau_j\} \frac{1}{N} \sum_{i=1}^N \Psi_i \Psi'_i$$

$\mathbf{J}(\cdot)$  can be estimated as

$$\hat{\mathbf{J}}(\tau) = \frac{1}{Nh_N} \sum_i^N K \left\{ \frac{-\widehat{\epsilon}_i(\tau)}{h_n} \right\} \Psi_i[\mathbf{d}'_i, \mathbf{x}'_i]$$

where  $\widehat{\epsilon}_i(\tau) = y_i - \mathbf{d}'_i\widehat{\alpha(\tau)} - \mathbf{x}'_i\widehat{\beta(\tau)}$ ,  $K(\cdot)$  is a kernel function, and  $h_n$  is the bandwidth.

`vce(vctype, kernel())` specifies the kernel function form  $K(\cdot)$ . See [R] `kdensity` for the function forms of the eight kernels.

`vce(vctype, bwidth())` specifies which bandwidth to use: `silverman` specifies to use  $h_s$ , `hshether` specifies to use  $h_k$  with  $h_1$  replaced by  $h_{hs}$ , and `bofinger` specifies to use  $h_k$  with  $h_1$  replaced by  $h_{bo}$ .

Silverman's rule of thumb bandwidth is

$$h_s = 0.9 \min \left\{ \widehat{\sigma(\hat{\epsilon})}, \frac{M}{1.349} \right\} N^{-\frac{1}{5}}$$

where  $\widehat{\sigma(\hat{\epsilon})}$  is the standard deviation of  $\hat{\epsilon}$  and  $M$  is the interquartile range of  $\hat{\epsilon}$ .

The bandwidth in Koenker (2005, 81) is

$$h_k = \min \left\{ \widehat{\sigma(\hat{\epsilon})}, \frac{M}{1.349} \right\} \{ \Phi^{-1}(\tau + h_1) - \Phi^{-1}(\tau - h_1) \}$$

where  $\Phi^{-1}(\cdot)$  is the inverse cumulative standard normal distribution and  $h_1$  can be one of the bandwidths in Hall and Sheather (1988) ( $h_{hs}$ ) or Bofinger (1975) ( $h_{bo}$ ). In particular,

$$h_{hs} = N^{-1/3} \Phi^{-1} \left( 1 - \frac{\alpha}{2} \right)^{2/3} \left[ \frac{3}{2} \times \frac{\phi \{ \Phi^{-1}(\tau) \}^2}{2\Phi^{-1}(\tau)^2 + 1} \right]^{1/3}$$

$$h_{bo} = N^{-1/5} \left[ \frac{9}{2} \times \frac{\phi \{ \Phi^{-1}(\tau) \}^4}{\{ 2\Phi^{-1}(\tau)^2 + 1 \}^2} \right]^{1/5}$$

where  $\phi(\cdot)$  is the standard normal probability density function.

## Acknowledgments

We thank David M. Kaplan of the Department of Economics at the University of Missouri for the helpful discussions and suggestions.

Stata has an active research community adding features to the area of instrumental-variables quantile regression. We would like to acknowledge their previous and ongoing contributions to this area: `sivqqr` by David M. Kaplan; `ivqreg2` by J. A. F. Machado and J. M. C. Santos Silva; `cqiv` by Victor Chernozhukov, Ivan Fernández-Val, Sukjin Han, and Amanda Kowalski; and many more. Type `search instrumental variables quantile regression` to see Stata's official and community-contributed features for instrumental-variables quantile regression.

## Postestimation commands

The following postestimation commands are of special interest after `ivqregress`:

| Command                        | Description                                                             |
|--------------------------------|-------------------------------------------------------------------------|
| <code>estat coefplot</code>    | plot coefficients and their confidence intervals at different quantiles |
| <code>estat endogeneity</code> | perform tests of endogeneity                                            |
| * <code>estat dualci</code>    | report dual confidence intervals for endogenous variable                |
| * <code>estat waldplot</code>  | plot Wald statistics corresponding to each grid point                   |

\*`estat dualci` and `estat waldplot` work only after `ivqregress iqr`.

The following postestimation commands are also available:

| Command                      | Description                                                                                       |
|------------------------------|---------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                               |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                      |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                |
| <code>estimates</code>       | cataloging estimation results                                                                     |
| <code>etable</code>          | table of estimation results                                                                       |
| <code>forecast</code>        | dynamic forecasts and simulations                                                                 |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters    |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                           |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters |
| <code>predict</code>         | linear predictions and residuals                                                                  |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions              |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                              |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                |

# predict

## Description for predict

`predict` creates a new variable containing predictions such as linear predictors and residuals.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic equation([eqno])]]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

---

Main

|                        |                               |
|------------------------|-------------------------------|
| <code>xb</code>        | linear predictor; the default |
| <code>residuals</code> | residuals                     |

---

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`xb`, the default, calculates the linear predictor.

`residuals` calculates the residuals, that is,  $y_j - \mathbf{x}_j\mathbf{b}$ .

`equation([eqno])` specifies the equation to which you are making the calculation.

`equation()` is filled in with one *eqno*. `equation(#1)` would mean that the calculation is to be made for the first equation, `equation(#2)` would mean the second, and so on. You could also refer to the equations by their names. `equation(p50)` would refer to the equation named p50 and `equation(p90)` to the equation named p90.

If you do not specify `equation()`, results are the same as if you had specified `equation(#1)`.

# margins

## Description for margins

`margins` estimates margins of response for linear predictors.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [options]
```

| <i>statistic</i>              | Description                   |
|-------------------------------|-------------------------------|
| <code>xb</code>               | linear predictor; the default |
| <code><u>r</u>esiduals</code> | not allowed with margins      |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## estat

### Description for estat

`estat coefplot` plots the estimated coefficients and their confidence intervals (CIs) after `ivqregress`.

`estat endogeffects` tests four hypotheses for the coefficients on the endogenous variables; see [Chernozhukov and Hansen \(2006\)](#). In particular, `estat endogeffects` provides tests for the following null hypotheses:

1. No effect: the endogenous variables do not affect the outcome variable.
2. Constant effect: the effects of the endogenous variables do not vary across estimated quantiles.
3. Dominance: the effects of the endogenous variables are greater than 0 across estimated quantiles.
4. Exogeneity: the variables are exogenous instead of endogenous.

`estat dualci` computes the dual CIs for the coefficients on the endogenous variable (one for each quantile) after `ivqregress iqr`; see [Chernozhukov and Hansen \(2008\)](#). The dual CI is robust to the weak instruments, and it is usually wider than the traditional CI.

`estat waldplot` plots the Wald statistic corresponding to each grid point after `ivqregress iqr`.

### Menu for estat

Statistics > Postestimation

### Syntax for estat

*Plot coefficients and their CIs at different quantiles*

```
estat coefplot [varname] [, coefplot_options]
```

*Perform tests of endogeneity*

```
estat endogeffects [varlist] [, endogeffects_options]
```

*Report dual CIs for endogenous variable*

```
estat dualci [, level(#) display_options]
```

*Plot Wald statistics corresponding to each grid point*

```
estat waldplot [, waldplot_options]
```

*varname* is one of the endogenous regressors or exogenous variables specified when fitting `ivqregress`.

By default, *varname* is the endogenous variable specified with `ivqregress iqr` or the first endogenous variable specified with `ivqregress smooth`.

*varlist* contains one or more of the endogenous variables specified when fitting a model with `ivqregress`; the default is the first endogenous variable.

| <i>coefplot_options</i>                                        | Description                                                                                 |
|----------------------------------------------------------------|---------------------------------------------------------------------------------------------|
| <code>nocl</code>                                              | do not plot the CIs                                                                         |

| <i><a href="#">tway_options</a></i>                         | any options other than <code>by()</code> documented in <a href="#">[G-3] twoway_options</a> |

## Options for estat

Options for `estat` are presented under the following headings:

*Options for estat coefplot*  
*Options for estat endogeffects*  
*Options for estat dualci*  
*Options for estat waldplot*

### Options for estat coefplot

`nocl` removes plots of the pointwise CIs. The default is to plot the CIs.

`no2s1s` removes the plot of the 2SLS estimates. The default is to plot the 2SLS reference line.

#### Plot

`connect_options` specify how points on a graph are to be connected; [G-3] *connect\_options*.

`marker_options` affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker\_options*.

#### CI plot

`ciopts` (*area\_options*) affects rendition of the pointwise CIs; see [G-3] *area\_options*.

#### Line options

`lineopts` (*cline\_options*) affects rendition of reference line identifying the 2SLS estimates; see [G-3] *cline\_options*.

#### Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] *twoway\_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title\_options*) and for saving the graph to disk (see [G-3] *saving\_option*).

### Options for estat endogeffects

`all` provides tests for all the four hypotheses, which is the default. If this option is specified with one of the options `noeffect`, `constant`, `dominance`, or `exogeneity`, then tests for all four hypotheses will be performed.

`noeffect` provides a test for the null hypothesis of no effect, that is, a test that the specified endogenous variables do not affect the outcome variable.

`constant` provides a test for the null hypothesis of constant effect, that is, a test that the effects of the specified endogenous variables do not vary across estimated quantiles.

`dominance` provides a test for the null hypothesis of dominance, that is, a test that the effects of the specified endogenous variables are greater than 0 across estimated quantiles.

`exogeneity` provides a test for the null hypothesis of exogeneity, that is, a test that the specified variables are exogenous instead of endogenous.

`level(#)` specifies the confidence level, as a percentage, for CIs. The default is `level(95)` or as set by `set level`; see [U] 20.8 *Specifying the width of confidence intervals*.

`rseed(#)` sets the random-number seed. Specifying this option makes the results reproducible because the critical values are drawn from a bootstrap sample.

`reps(#)` specifies the number of bootstrap replications to get the critical values of the test. The default is `reps(100)`.

### Options for `estat dualci`

`level(#)` specifies the confidence level, as a percentage, for the dual CIs. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] Estimation options.

### Options for `estat waldplot`

`quantile(#)` specifies to plot the Wald statistics for each grid points in the `#th` quantile estimation; the default is the first equation.

`level(#)` specifies the confidence level, as a percentage, for the dual CIs. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.

Plot

`connect_options` specify how points on a graph are to be connected; [G-3] *connect\_options*.

`marker_options` affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker\_options*.

CI plot

`ciopts(area_options)` affects rendition of the pointwise dual CI plot; see [G-3] *area\_options*.

Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] *twoway\_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title\_options*) and for saving the graph to disk (see [G-3] *saving\_option*).

## Remarks and examples

For examples of using `estat coefplot` and `estat endogeffects`, see [example 3](#) in [R] `ivqregress`. For an example of using `estat dualci`, see [example 1](#) in [R] `ivqregress`. For an example of using `estat waldplot`, see [example 4](#) in [R] `ivqregress`.

### ▷ Example 1

In [example 1](#) in [R] `ivqregress`, we fit an instrumental-variables quantile regression (IVQR) model to estimate the effects of 401(k) participation on the conditional median of the net financial assets. Suppose that now we want to know the median of the net financial assets when everyone does or does not participate in a 401(k) conditional on other covariates; we can use `margins` to find the answer.

We specify `i.p401k` immediately after margins to obtain the median of the assets under 401(k) participation and under no 401(k) participation. The `at()` option specifies the values of other covariates when computing the median. In particular, the continuous variables such as `income`, `age`, `familysize`, and `educ` are fixed at the sample mean, and people are assumed to be married, participate in an IRA, receive pension benefits, and own a home.

```
. use https://www.stata-press.com/data/r19/assets2
(Excerpt from Chernozhukov and Hansen (2004))
. ivqregress iqr assets (i.p401k = i.e401k) income age familysize
> i.married i.ira i.pension i.ownhome educ
(output omitted)
. margins i.p401k, at((mean) income age familysize educ
> married = 1 ira = 1 pension = 1 ownhome = 1)
Adjusted predictions Number of obs = 9,913
Model VCE: Robust
Expression: Linear predictor, predict()
At: income = 37208.4 (mean)
 age = 41.05891 (mean)
 familysize = 2.865328 (mean)
 married = 1
 ira = 1
 pension = 1
 ownhome = 1
 educ = 13.20629 (mean)
```

|       | Delta-method |           |       |       |                      |
|-------|--------------|-----------|-------|-------|----------------------|
|       | Margin       | std. err. | z     | P> z  | [95% conf. interval] |
| p401k |              |           |       |       |                      |
| No    | 23681.37     | 1007.612  | 23.50 | 0.000 | 21706.49 25656.26    |
| Yes   | 28994.77     | 1123.076  | 25.82 | 0.000 | 26793.58 31195.96    |

The results show that the conditional median of assets when everyone participates in a 401(k) is \$28,995. In contrast, the conditional median of assets when no one participates in a 401(k) is only \$23,681. The difference between these two medians is \$5,313, which is the quantile treatment effect of `p401k` and is the same as the coefficient's value.

◀

## Stored results

`estat endogeffects` stores the following in `r()`:

### Scalars

`r(N_reps)`            number of replications  
`r(level)`             confidence level

### Macros

`r(endog)`            tested endogenous regressors

### Matrices

`r(table)`            matrix containing test statistics and critical values

estat dualci stores the following in `r()`:

Scalars

`r(N)` number of observations  
`r(level)` confidence level for the dual CI

Matrices

`r(table)` matrix containing test statistics,  $p$ -values, and confidence errors, test statistics,  $p$ -values, and confidence intervals

## Methods and formulas

Methods and formulas are presented under the following headings:

*Tests of effects of endogenous variables*  
*Dual CI*

## Tests of effects of endogenous variables

estat endogeffects implements the general inference procedure outlined in section 4 of Chernozhukov and Hansen (2006). It tests the following null hypotheses:

1. No effect: the endogenous variables do not affect the outcome variable.
2. Constant effect: the effects of the endogenous variables do not vary across estimated quantiles.
3. Dominance: the effects of the endogenous variables are greater than 0 across estimated quantiles.
4. Exogeneity: the variables are exogenous instead of endogenous.

It is convenient to write each null hypothesis in the following form:

$$\mathbf{R}(\tau)\{\boldsymbol{\theta}(\tau) - \mathbf{r}(\tau)\} = 0 \quad \text{for each } \tau \in T$$

where  $\mathbf{R}(\tau)$  is a  $q \times p$  matrix of rank  $q$  when  $q$  is smaller than the dimension of  $\boldsymbol{\theta}(\tau)$ .  $\boldsymbol{\theta}(\tau)$  is the  $p \times 1$  coefficient vector for the IVQR model in the  $\tau$ th quantile,  $\mathbf{r}(\tau) \in R^p$ , and  $T$  is a set of estimated quantile indexes. This form is different from the classical setting because  $\boldsymbol{\theta}(\cdot)$  and  $\mathbf{r}(\cdot)$  are functions, which need to be estimated in some cases.

Based on the IVQR model estimates  $\hat{\boldsymbol{\theta}}(\cdot)$ , we focus on the basic inference process

$$\mathbf{v}_n(\cdot) = \mathbf{R}(\cdot)\{\hat{\boldsymbol{\theta}}(\cdot) - \hat{\mathbf{r}}(\cdot)\}$$

where  $\hat{\mathbf{r}}(\cdot)$  is either a vector of constants or a vector of estimates from the classical quantile regression. We use the Kolmogorov–Smirnov statistic  $S_n = f\{\sqrt{n}\mathbf{v}_n(\cdot)\}$ , which is a function of  $\mathbf{v}_n(\cdot)$ .

$$S_n = \sqrt{n} \sup_{\tau \in T} \|\mathbf{v}_n(\tau)\|_{\widehat{\boldsymbol{\Lambda}}(\tau)}$$

where  $\|\mathbf{v}\|_{\boldsymbol{\Lambda}} = \sqrt{\mathbf{v}'\mathbf{A}\mathbf{v}}$ . For the choice of  $\widehat{\boldsymbol{\Lambda}}(\tau)$ , see section 4.4 in Chernozhukov and Hansen (2006). In essence,  $\widehat{\boldsymbol{\Lambda}}(\tau)$  is the empirical variance of the estimating scores implied by the IVQR model.

The null hypothesis is rejected if

$$S_n > c(1 - \alpha)$$

where the critical value  $c(1 - \alpha)$  with confidence level  $1 - \alpha$  can be obtained using the bootstrap resampling procedure described in section 4.3 of Chernozhukov and Hansen (2006).

Now we describe the formal definition of the four hypotheses. For notational simplicity, we assume that there is one endogenous variable but the case of multiple endogenous variables can be extended easily. Let  $\alpha(\tau)$  denote the endogenous coefficient for the  $\tau$ th quantile estimation. In this case,  $\mathbf{R} = (1, 0, \dots, 0)$  for the four hypotheses considered.

1. No effect: the null hypothesis is that the endogenous variable has no impact on the outcome:  $\alpha(\tau) = 0$ . In this case,

$$\begin{aligned} H_0 : \quad & \alpha(\tau) = 0 \quad \text{for all } \tau \in T \\ H_1 : \quad & \alpha(\tau) \neq 0 \quad \text{for some } \tau \in T \end{aligned}$$

and  $\hat{r}(\cdot) = 0$ .

2. Constant effect: the null hypothesis of a constant effect is that the endogenous variable only affects the location of the outcome but not other moments. That is,  $\alpha(\tau) = c$  for all  $\tau \in T$ , where  $c$  is a constant. In this case,

$$\begin{aligned} H_0 : \quad & \alpha(\tau) = c \quad \text{for all } \tau \in T \\ H_1 : \quad & \alpha(\tau) \neq c \quad \text{for some } \tau \in T \end{aligned}$$

and  $\hat{r}(\cdot)$  is the estimate of endogenous coefficient for one of the quantile indexes.

3. Dominance: the dominance test tests whether the effects of endogenous variable are unambiguously beneficial. That is,  $\alpha(\tau) > 0$  for all  $\tau \in T$ . For this hypothesis, we use the one-sided Kolmogorov–Smirnov statistic

$$S_n = \sqrt{n} \sup_{\tau \in T} \max(-\alpha(\tau), 0)$$

In this case,

$$\begin{aligned} H_0 : \quad & \alpha(\tau) > 0 \quad \text{for all } \tau \in T \\ H_1 : \quad & \alpha(\tau) \leq 0 \quad \text{for some } \tau \in T \end{aligned}$$

and  $\hat{r}(\cdot) = 0$ .

4. Exogeneity: if all the covariates are exogenous, we can fit the model by the regular quantile regression and denote  $\eta(\tau)$  as the quantile regression estimator. The difference between  $\theta(\tau)$  and  $\eta(\tau)$  can be used to formulate a Hausman test of exogeneity. In this case, the null and alternative are defined as

$$\begin{aligned} H_0 : \quad & \alpha(\tau) = \mathbf{R}\eta(\tau) \quad \text{for all } \tau \in T \\ H_1 : \quad & \alpha(\tau) \neq \mathbf{R}\eta(\tau) \quad \text{for some } \tau \in T \end{aligned}$$

and  $\hat{\mathbf{r}}(\tau) = \hat{\eta}(\tau)$ , where  $\hat{\eta}(\tau)$  is the regular quantile regression estimate.

## Dual CI

`estat dualci` computes the dual CI proposed in Chernozhukov and Hansen (2008) for the coefficient on the endogenous variable in the IVQR model. The dual CI is robust to the weak instrument, and it is usually wider than the classical CI. `estat dualci` is allowed only after `ivqregress iqr`. If you have not read about the methods for the inverse quantile regression (IQR) estimator, see *The IQR estimator in Methods and formulas* of [R] `ivqregress`.

Suppose we know the true value of the coefficient on the endogenous covariates, which we denote as  $\alpha(\tau)$ , and let  $W_n\{\alpha(\tau)\}$  be the Wald statistic for the coefficient on the instruments in the auxiliary quantile regression. Then by proposition 1 in Chernozhukov and Hansen (2008),

$$W_n\{\alpha(\tau)\} \rightarrow_d \chi^2(1)$$

and for the confidence region  $CR_p\{\alpha(\tau)\} = \{\alpha \in A : W_n(\alpha) < c_p\}$ , where  $P\{\chi^2(1) < c_p\} = p$ , and

$$P[\alpha(\tau) \in CR_p\{\alpha(\tau)\}] = P[W_n\{\alpha(\tau)\} < c_p] = p$$

Intuitively,  $W_n\{\alpha(\tau)\}$  is the Wald statistic for testing whether the coefficients for the instruments are 0. When  $\alpha$  equals the true value  $\alpha(\tau)$ ,  $W(\cdot)$  is  $\chi^2$  distributed with the degree of freedom of 1. Thus, a valid CI for  $\alpha$  can be constructed by the inversion of the Wald statistic. That is,

$$CR_p\{\alpha(\tau)\} = \{\alpha \in A : W_n(\alpha) < c_p\}$$

covers the true value of  $\alpha(\tau)$  with probability approaching  $p$ .

In practice, the dual CI is constructed by the lower and upper limits of the grid points such that the corresponding Wald statistic is smaller than the critical value  $c_p$ .

## Description

`ivregress` fits linear models where one or more of the regressors are endogenously determined. `ivregress` supports estimation via two-stage least squares (2SLS), limited-information maximum likelihood (LIML), and generalized method of moments (GMM).

## Quick start

2SLS estimation of a linear regression of `y1` on `x1` and endogenous regressor `y2` that is instrumented by `z1`

```
ivregress 2sls y1 x1 (y2 = z1)
```

Same as above, but with two endogenous regressors, `y2` and `y3` instrumented by `z1` and `z2`

```
ivregress 2sls y1 x1 (y2 y3 = z1 z2)
```

Same as above, but absorbing indicator variables for the levels of `cvar1` and `cvar2`

```
ivregress 2sls y1 x1 (y2 y3 = z1 z2), absorb(cvar1 cvar2)
```

With robust standard errors

```
ivregress 2sls y1 x1 (y2 y3 = z1 z2), vce(robust)
```

Report small-sample statistics

```
ivregress 2sls y1 x1 (y2 y3 = z1 z2), small
```

Use LIML estimation

```
ivregress liml y1 x1 (y2 y3 = z1 z2)
```

Use GMM estimation

```
ivregress gmm y1 x1 (y2 y3 = z1 z2)
```

Also specify a weight matrix that allows for correlation within clusters identified by `cvar`

```
ivregress gmm y1 x1 (y2 y3 = z1 z2), wmatrix(cluster cvar)
```

## Menu

Statistics > Endogenous covariates > Linear regression with endogenous covariates

## Syntax

```
ivregress estimator depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight]
[, options]
```

*varlist<sub>1</sub>* is the list of exogenous variables.

*varlist<sub>2</sub>* is the list of endogenous variables.

*varlist<sub>iv</sub>* is the list of exogenous variables used with *varlist<sub>1</sub>* as instruments for *varlist<sub>2</sub>*.

<sup>1</sup>These options may be specified only with `2s1s`.

<sup>2</sup>These options may be specified only with `gmm`.

<sup>3</sup>These options may be specified only with `igmm`.

<sup>4</sup>These options may be specified only with `igmm` or `2s1s` and `absorb()`.

<sup>†</sup>Ignored if only one absorbed variable is specified.

`varlist1`, `varlist2`, and `varlistiv` may contain factor variables; see [U] 11.4.3 Factor variables.

`depvar`, `varlist1`, `varlist2`, and `varlistiv` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayesboot`, `bootstrap`, `by`, `collect`, `fmm`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [FMM] `fmm`: `ivregress`.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`aweight`s are not allowed with the `jackknife` prefix; see [R] `jackknife`.

`absorb()`, `dfabsorb`, `hascons`, `vce()`, `noheader`, `depname()`, and `weights` are not allowed with the `svy` prefix; see [SVY] `svy`.

`fweights`, `ifweights`, and `pweights` are not allowed with `vce(hac)`.

`aweight`s, `fweights`, `ifweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

`perfect` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

`absorb(varlist [ , method ])` specifies the categorical variables to be absorbed. The results are adjusted as if indicator variables for each level of each variable in `varlist` were included in the regression.

The absorption of categorical variables involves projecting the `depvar` and all variables in `varlist1`, `varlist2`, and `varlistiv` via an alternating projection method (APM) iterative algorithm. `method` specifies the APM and is one of `halperin` or `cimmino`.

`halperin`, the default, uses the product of the projection matrices.

`cimmino` uses the mean of the projection matrices.

The two methods typically perform similarly. See [Stammann \(2018\)](#) for details.

`method` is ignored if only one absorbed variable is specified.

`absorb()` may not be combined with `vce(hac)`.

`dfabsorb` adjusts the degrees of freedom to account for collinearity among absorbed variables. The default degrees of freedom assumes that all absorbed variables are independent. This option is ignored if only one absorbed variable is specified in `absorb()`.

`noconstant`; see [R] Estimation options.

`hascons` indicates that a user-defined constant or its equivalent is specified among the independent variables.

### GMM

`wmatrix(wmtype)` specifies the type of weight matrix to be used in conjunction with the GMM estimator.

`wmatrix(robust)`, the default, requests a weight matrix that is optimal when the error term is heteroskedastic.

`wmatrix(cluster clustvar)` requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by *clustvar*.

`wmatrix(hac hacspec)` requests a heteroskedasticity- and autocorrelation-consistent (HAC) weight matrix. The full syntax of *hacspec* is one of the following:

`wmatrix(hac kernel [#])` requests a HAC weight matrix using the specified kernel (see below) with optional # lags. The bandwidth of a kernel is equal to # + 1. If # is not specified, a kernel with  $N - 2$  lags is used, where  $N$  is the sample size.

`wmatrix(hac kernel opt [#])` requests a HAC weight matrix using the specified kernel (see below), and the lag order is selected using Newey and West's (1994) optimal lag-selection algorithm. # is an optional tuning parameter that affects the lag order selected; see the [discussion](#) in *Methods and formulas*.

*kernel* may be one of the following:

`bartlett` or `nwest` requests the Bartlett (Newey–West) kernel.

`parzen` or `gallant` requests the Parzen (Gallant 1987) kernel.

`quadraticspectral` or `andrews` requests the quadratic spectral (Andrews 1991) kernel.

`wmatrix(unadjusted)` requests a weight matrix that is suitable when the errors are homoskedastic. The GMM estimator with this weight matrix is equivalent to the 2SLS estimator.

`center` requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

`igmm` requests that the iterative GMM estimator be used instead of the default two-step GMM estimator. Convergence is declared when the relative change in the parameter vector from one iteration to the next is less than `eps()` or the relative change in the weight matrix is less than `weps()`.

`eps(#)` specifies the convergence criterion for successive parameter estimates when the iterative GMM estimator is used. The default is `eps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `eps()` and the relative difference between successive estimates of the weight matrix is less than `weps()`.

`weps(#)` specifies the convergence criterion for successive estimates of the weight matrix when the iterative GMM estimator is used. The default is `weps(1e-6)`. Convergence is declared when the relative difference between successive parameter estimates is less than `eps()` and the relative difference between successive estimates of the weight matrix is less than `weps()`.

---

#### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [\[R\] vce\\_option](#).

`vce(unadjusted)`, the default for `2s1s` and `liml`, specifies that an unadjusted (nonrobust) VCE matrix be used. The default for `gmm` is based on the *wmtype* specified in the `wmatrix()` option; see `wmatrix()` above. If `wmatrix()` is specified with `gmm` but `vce()` is not, then *vcetype* is set equal to *wmtype*. To override this behavior and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`.

`vce(hac hacspec)` specifies that a HAC covariance matrix be used. The syntax is identical to that for `wmatrix()`. `vce(hac)` may not be combined with `absorb()`.

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the first-stage regression results be displayed.

`small` requests that the degrees-of-freedom adjustment  $N/(N - k)$  be made to the variance–covariance matrix of parameters and that small-sample  $F$  and  $t$  statistics be reported, where  $N$  is the sample size and  $k$  is the number of parameters estimated. By default, no degrees-of-freedom adjustment is made, and Wald and  $z$  statistics are reported. Even with this option, no degrees-of-freedom adjustment is made to the weight matrix when the GMM estimator is used.

`noheader` suppresses the display of the summary statistics at the top of the output, displaying only the coefficient table.

`depname(depname)` is used only in programs and ado-files that use `ivregress` to fit models other than instrumental-variables regression. `depname()` may be specified only at estimation time. *depname* is recorded as the identity of the dependent variable, even though the estimates are calculated using *depvar*. This method affects the labeling of the output—not the results calculated—but could affect later calculations made by `predict`, where the residual would be calculated as deviations from *depname* rather than *depvar*. `depname()` is most typically used when *depvar* is a temporary variable (see [P] [macro](#)) used as a proxy for *depname*.

`eform(string)` is used only in programs and ado-files that use `ivregress` to fit models other than instrumental-variables regression. `eform()` specifies that the coefficient table be displayed in “exponentiated form”, as defined in [R] [Maximize](#), and that *string* be used to label the exponentiated coefficients in the table.

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

## Optimization

*optimization\_options*: `iterate(#)`, `[no]log`, and `tolerance(#)`. `iterate()` specifies the maximum number of iterations to perform in conjunction with the iterative GMM estimator. The default is the number set using `set maxiter`, which is 300 by default. `log/nolog` specifies whether to show the iteration log; see `set iterlog` in [R] [set iter](#). `tolerance()` is allowed only with `2sls` and the `absorb()` option and specifies the projection tolerance. These options are seldom used.

The following options are available with `ivregress` but are not shown in the dialog box:

`perfect` requests that `ivregress` not check for collinearity between the endogenous regressors and excluded instruments, allowing one to specify “perfect” instruments. This option cannot be used with the LIML estimator. This option may be required when using `ivregress` to implement other estimators.

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

`ivregress` performs instrumental-variables regression and weighted instrumental-variables regression. For a general discussion of instrumental variables, see [Baum \(2006\)](#), [Cameron and Trivedi \(2005; 2022, chap. 7\)](#) [Davidson and MacKinnon \(1993\)](#), [Greene \(2018, chap. 8\)](#), and [Wooldridge \(2010, 2020\)](#). See [Hall \(2005\)](#) for a lucid presentation of GMM estimation. [Angrist and Pischke \(2009, chap. 4\)](#) offer

a casual yet thorough introduction to instrumental-variables estimators, including their use in estimating treatment effects. Some of the earliest work on simultaneous systems can be found in Cowles Commission monographs—[Koopmans and Marschak \(1950\)](#) and [Koopmans and Hood \(1953\)](#)—with the first developments of 2SLS appearing in [Theil \(1953\)](#) and [Basmann \(1957\)](#). However, [Stock and Watson \(2019, 401–402\)](#) present an example of the method of instrumental variables that was first published in 1928 by Philip Wright.

The syntax for `ivregress` assumes that you want to fit one equation from a system of equations or an equation for which you do not want to specify the functional form for the remaining equations of the system. To fit a full system of equations, using either 2SLS equation-by-equation or three-stage least squares, see [\[R\] reg3](#). An advantage of `ivregress` is that you can fit one equation of a multiple-equation system without specifying the functional form of the remaining equations.

Formally, the model fit by `ivregress` is

$$y_i = \mathbf{y}_i\boldsymbol{\beta}_1 + \mathbf{x}_{1i}\boldsymbol{\beta}_2 + u_i \quad (1)$$

$$\mathbf{y}_i = \mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2 + \mathbf{v}_i \quad (2)$$

Here  $y_i$  is the dependent variable for the  $i$ th observation,  $\mathbf{y}_i$  represents the endogenous regressors (`varlist2` in the syntax diagram),  $\mathbf{x}_{1i}$  represents the included exogenous regressors (`varlist1` in the syntax diagram), and  $\mathbf{x}_{2i}$  represents the excluded exogenous regressors (`varlistiv` in the syntax diagram).  $\mathbf{x}_{1i}$  and  $\mathbf{x}_{2i}$  are collectively called the instruments.  $u_i$  and  $\mathbf{v}_i$  are zero-mean error terms, and the correlations between  $u_i$  and the elements of  $\mathbf{v}_i$  are presumably nonzero.

The rest of the discussion is presented under the following headings:

[2SLS and LIML estimators](#)

[GMM estimator](#)

[Video example](#)

## 2SLS and LIML estimators

The most common instrumental-variables estimator is 2SLS.

### ▷ Example 1: 2SLS estimator

We have state data from the 1980 census on the median dollar value of owner-occupied housing (`hshngval`) and the median monthly gross rent (`rent`). We want to model `rent` as a function of `hshngval` and the percentage of the population living in urban areas (`pcturban`):

$$\text{rent}_i = \beta_0 + \beta_1 \text{hshngval}_i + \beta_2 \text{pcturban}_i + u_i$$

where  $i$  indexes states and  $u_i$  is an error term.

Because random shocks that affect rental rates in a state probably also affect housing values, we treat `hshngval` as endogenous. We believe that the correlation between `hshngval` and  $u$  is not equal to zero. On the other hand, we have no reason to believe that the correlation between `pcturban` and  $u$  is nonzero, so we assume that `pcturban` is exogenous.

Because we are treating `hshngval` as an endogenous regressor, we must have one or more additional variables available that are correlated with `hshngval` but uncorrelated with  $u$ . Moreover, these excluded exogenous variables must not affect `rent` directly, because if they do then they should be included in the regression equation we specified above. In our dataset, we have a variable for family income (`faminc`) and for region of the country (`region`) that we believe are correlated with `hshngval` but not the error term. Together, `pcturban`, `faminc`, and factor variables `2.region`, `3.region`, and `4.region` constitute our set of instruments.

To fit the equation in Stata, we specify the dependent variable and the list of included exogenous variables. In parentheses, we specify the endogenous regressors, an equal sign, and the excluded exogenous variables. Only the additional exogenous variables must be specified to the right of the equal sign; the exogenous variables that appear in the regression equation are automatically included as instruments.

Here we fit our model with the 2SLS estimator:

```
. use https://www.stata-press.com/data/r19/hsng
(1980 Census housing data)
. ivregress 2sls rent pcturban (hsngval = faminc i.region)
Instrumental-variables 2SLS regression Number of obs = 50
 Wald chi2(2) = 90.76
 Prob > chi2 = 0.0000
 R-squared = 0.5989
 Root MSE = 22.166
```

| rent     | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|----------|-------------|-----------|------|-------|----------------------|----------|
| hsngval  | .0022398    | .0003284  | 6.82 | 0.000 | .0015961             | .0028836 |
| pcturban | .081516     | .2987652  | 0.27 | 0.785 | -.504053             | .667085  |
| _cons    | 120.7065    | 15.22839  | 7.93 | 0.000 | 90.85942             | 150.5536 |

Endogenous: hsngval

Exogenous: pcturban faminc 2.region 3.region 4.region

As we would expect, states with higher housing values have higher rental rates. The proportion of a state's population that is urban does not have a significant effect on rents.

## □ Technical note

In a simultaneous-equations framework, we could write the model we just fit as

$$\begin{aligned} \text{hsngval}_i &= \pi_0 + \pi_1 \text{faminc}_i + \pi_2 \text{2.region}_i + \pi_3 \text{3.region}_i + \pi_4 \text{4.region}_i + v_i \\ \text{rent}_i &= \beta_0 + \beta_1 \text{hsngval}_i + \beta_2 \text{pcturban}_i + u_i \end{aligned}$$

which here happens to be recursive (triangular), because `hsngval` appears in the equation for `rent` but `rent` does not appear in the equation for `hsngval`. In general, however, systems of simultaneous equations are not recursive. Because this system is recursive, we could fit the two equations individually via OLS if we were willing to assume that  $u$  and  $v$  were independent. For a more detailed discussion of triangular systems, see [Kmenta \(1997, 719–720\)](#).

Historically, instrumental-variables estimation and systems of simultaneous equations were taught concurrently, and older textbooks describe instrumental-variables estimation solely in the context of simultaneous equations. However, in recent decades, the treatment of endogeneity and instrumental-variables estimation has taken on a much broader scope, while interest in the specification of complete systems of simultaneous equations has waned. Most recent textbooks, such as [Cameron and Trivedi \(2005\)](#), [Davidson and MacKinnon \(1993\)](#), and [Wooldridge \(2010, 2020\)](#), treat instrumental-variables estimation as an integral part of the modern economists' toolkit and introduce it long before shorter discussions on simultaneous equations.

In addition to the 2SLS member of the  $\kappa$ -class estimators, `ivregress` implements the LIML estimator. Both theoretical and Monte Carlo exercises indicate that the LIML estimator may yield less bias and confidence intervals with better coverage rates than the 2SLS estimator. See [Poi \(2006\)](#) and [Stock, Wright, and Yogo \(2002\)](#) (and the papers cited therein) for Monte Carlo evidence.

## ▷ Example 2: LIML estimator

Here we refit our model with the LIML estimator:

```
. ivregress liml rent pcturban (hsngval = faminc i.region)
Instrumental-variables LIML regression Number of obs = 50
 Wald chi2(2) = 75.71
 Prob > chi2 = 0.0000
 R-squared = 0.4901
 Root MSE = 24.992
```

| rent     | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|----------|-------------|-----------|-------|-------|----------------------|----------|
| hsngval  | .0026686    | .0004173  | 6.39  | 0.000 | .0018507             | .0034865 |
| pcturban | -.1827391   | .3571132  | -0.51 | 0.609 | -.8826681            | .5171899 |
| _cons    | 117.6087    | 17.22625  | 6.83  | 0.000 | 83.84587             | 151.3715 |

Endogenous: hsngval

Exogenous: pcturban faminc 2.region 3.region 4.region

These results are qualitatively similar to the [2SLS results](#), although the coefficient on `hsngval` is about 19% higher.

◀

## GMM estimator

Since the celebrated paper of [Hansen \(1982\)](#), the GMM has been a popular method of estimation in economics and finance, and it lends itself well to instrumental-variables estimation. The basic principle is that we have some *moment* or *orthogonality* conditions of the form

$$E(\mathbf{z}_i u_i) = \mathbf{0} \quad (3)$$

From (1), we have  $u_i = y_i - \mathbf{y}_i \boldsymbol{\beta}_1 - \mathbf{x}_{1i} \boldsymbol{\beta}_2$ . What are the elements of the instrument vector  $\mathbf{z}_i$ ? By assumption,  $\mathbf{x}_{1i}$  is uncorrelated with  $u_i$ , as are the excluded exogenous variables  $\mathbf{x}_{2i}$ , and so we use  $\mathbf{z}_i = [\mathbf{x}_{1i} \ \mathbf{x}_{2i}]$ . The moment conditions are simply the mathematical representation of the assumption that the instruments are exogenous—that is, the instruments are orthogonal to (uncorrelated with)  $u_i$ .

If the number of elements in  $\mathbf{z}_i$  is just equal to the number of unknown parameters, then we can apply the analogy principle to (3) and solve

$$\frac{1}{N} \sum_i \mathbf{z}_i u_i = \frac{1}{N} \sum_i \mathbf{z}_i (y_i - \mathbf{y}_i \boldsymbol{\beta}_1 - \mathbf{x}_{1i} \boldsymbol{\beta}_2) = \mathbf{0} \quad (4)$$

This equation is known as the method of moments estimator. Here, where the number of instruments equals the number of parameters, the method of moments estimator coincides with the 2SLS estimator, which also coincides with what has historically been called the indirect least-squares estimator (Judge et al. 1985, 595).

The “generalized” in GMM addresses the case in which the number of instruments (columns of  $\mathbf{z}_i$ ) exceeds the number of parameters to be estimated. Here there is no unique solution to the population moment conditions defined in (3), so we cannot use (4). Instead, we define the objective function

$$Q(\beta_1, \beta_2) = \left( \frac{1}{N} \sum_i \mathbf{z}_i u_i \right)' \mathbf{W} \left( \frac{1}{N} \sum_i \mathbf{z}_i u_i \right) \quad (5)$$

where  $\mathbf{W}$  is a positive-definite matrix with the same number of rows and columns as the number of columns of  $\mathbf{z}_i$ .  $\mathbf{W}$  is known as the weight matrix, and we specify its structure with the `wmatrix()` option. The GMM estimator of  $(\beta_1, \beta_2)$  minimizes  $Q(\beta_1, \beta_2)$ ; that is, the GMM estimator chooses  $\beta_1$  and  $\beta_2$  to make the moment conditions as close to zero as possible for a given  $\mathbf{W}$ . For a more general GMM estimator, see [R] `gmm`. `gmm` does not restrict you to fitting a single linear equation, though the syntax is more complex.

A well-known result is that if we define the matrix  $\mathbf{S}_0$  to be the covariance of  $\mathbf{z}_i u_i$  and set  $\mathbf{W} = \mathbf{S}_0^{-1}$ , then we obtain the optimal two-step GMM estimator, where by optimal estimator we mean the one that results in the smallest variance given the moment conditions defined in (3).

Suppose that the errors  $u_i$  are heteroskedastic but independent among observations. Then

$$\mathbf{S}_0 = E(\mathbf{z}_i u_i u_i \mathbf{z}_i') = E(u_i^2 \mathbf{z}_i \mathbf{z}_i')$$

and the sample analogue is

$$\hat{\mathbf{S}} = \frac{1}{N} \sum_i \hat{u}_i^2 \mathbf{z}_i \mathbf{z}_i' \quad (6)$$

To implement this estimator, we need estimates of the sample residuals  $\hat{u}_i$ . `ivregress gmm` obtains the residuals by estimating  $\beta_1$  and  $\beta_2$  by 2SLS and then evaluates (6) and sets  $\mathbf{W} = \hat{\mathbf{S}}^{-1}$ . Equation (6) is the same as the center term of the “sandwich” robust covariance matrix available from most Stata estimation commands through the `vce(robust)` option.

### ▷ Example 3: GMM estimator

Here we refit our model of rents by using the GMM estimator, allowing for heteroskedasticity in  $u_i$ :

```
. ivregress gmm rent pcturban (hsngval = faminc i.region), wmatrix(robust)
Instrumental-variables GMM regression Number of obs = 50
 Wald chi2(2) = 112.09
 Prob > chi2 = 0.0000
 R-squared = 0.6616
GMM weight matrix: Robust Root MSE = 20.358
```

|          |             | Robust    |       |       |                      |          |
|----------|-------------|-----------|-------|-------|----------------------|----------|
| rent     | Coefficient | std. err. | z     | P> z  | [95% conf. interval] |          |
| hsngval  | .0014643    | .0004473  | 3.27  | 0.001 | .0005877             | .002341  |
| pcturban | .7615482    | .2895105  | 2.63  | 0.009 | .1941181             | 1.328978 |
| _cons    | 112.1227    | 10.80234  | 10.38 | 0.000 | 90.95052             | 133.2949 |

Endogenous: hsngval

Exogenous: pcturban faminc 2.region 3.region 4.region

Because we requested that a heteroskedasticity-consistent weight matrix be used during estimation but did not specify the `vce()` option, `ivregress` reported standard errors that are robust to heteroskedasticity. Had we specified `vce(unadjusted)`, we would have obtained standard errors that would be correct only if the weight matrix  $\mathbf{W}$  does in fact converge to  $\mathbf{S}_0^{-1}$ .

## □ Technical note

Many software packages that implement GMM estimation use the same heteroskedasticity-consistent weight matrix we used in the [previous example](#) to obtain the optimal two-step estimates but do not use a heteroskedasticity-consistent VCE, even though they may label the standard errors as being “robust”. To replicate results obtained from other packages, you may have to use the `vce(unadjusted)` option. See [Methods and formulas](#) below for a discussion of robust covariance matrix estimation in the GMM framework. □

By changing our definition of  $\mathbf{S}_0$ , we can obtain GMM estimators suitable for use with other types of data that violate the assumption that the errors are independent and identically distributed. For example, you may have a dataset that consists of multiple observations for each person in a sample. The observations that correspond to the same person are likely to be correlated, and the estimation technique should account for that lack of independence. Say that in your dataset, people are identified by the variable `personid` and you type

```
. ivregress gmm ..., wmatrix(cluster personid)
```

Here `ivregress` estimates  $\mathbf{S}_0$  as

$$\hat{\mathbf{S}} = \frac{1}{N} \sum_{c \in C} \mathbf{q}_c \mathbf{q}_c'$$

where  $C$  denotes the set of clusters and

$$\mathbf{q}_c = \sum_{i \in c_j} \hat{u}_i \mathbf{z}_i$$

where  $c_j$  denotes the  $j$ th cluster. This weight matrix accounts for the within-person correlation among observations, so the GMM estimator that uses this version of  $\mathbf{S}_0$  will be more efficient than the estimator that ignores this correlation.

## ▷ Example 4: GMM estimator with clustering

We have data from the National Longitudinal Survey on young women’s wages as reported in a series of interviews from 1968 through 1988, and we want to fit a model of wages as a function of each woman’s age and age squared, job tenure, birth year, and level of education. We believe that random shocks that affect a woman’s wage also affect her job tenure, so we treat tenure as endogenous. As additional instruments, we use her union status, number of weeks worked in the past year, and a dummy indicating whether she lives in a metropolitan area. Because we have several observations for each woman (corresponding to interviews done over several years), we want to control for clustering on each person.

```
. use https://www.stata-press.com/data/r19/nlswork
(National Longitudinal Survey of Young Women, 14-24 years old in 1968)
. ivregress gmm ln_wage age c.age#c.age birth_yr grade
> (tenure = union wks_work msp), wmatrix(cluster idcode)

Instrumental-variables GMM regression Number of obs = 18,625
 Wald chi2(5) = 1807.17
 Prob > chi2 = 0.0000
 Root MSE = .46951

GMM weight matrix: Cluster (idcode)
 (Std. err. adjusted for 4,110 clusters in idcode)
```

| ln_wage     | Coefficient | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |           |
|-------------|-------------|---------------------|-------|-------|----------------------|-----------|
| tenure      | .099221     | .0037764            | 26.27 | 0.000 | .0918194             | .1066227  |
| age         | .0171146    | .0066895            | 2.56  | 0.011 | .0040034             | .0302259  |
| c.age#c.age | -.0005191   | .0001111            | -4.68 | 0.000 | -.0007366            | -.0003016 |
| birth_yr    | -.0085994   | .0021932            | -3.92 | 0.000 | -.012898             | -.0043008 |
| grade       | .071574     | .0029938            | 23.91 | 0.000 | .0657062             | .0774417  |
| _cons       | .8575071    | .1616274            | 5.31  | 0.000 | .5407231             | 1.174291  |

Endogenous: tenure

Exogenous: age c.age#c.age birth\_yr grade union wks\_work msp

Both job tenure and years of schooling have significant positive effects on wages.

◀

Time-series data are often plagued by serial correlation. In these cases, we can construct a weight matrix to account for the fact that the error in period  $t$  is probably correlated with the errors in periods  $t - 1$ ,  $t - 2$ , etc. A HAC weight matrix can be used to account for both serial correlation and potential heteroskedasticity.

To request a HAC weight matrix, you specify the `wmatrix(hac kernel [#|opt])` option. *kernel* specifies which of three kernels to use: `bartlett`, `parzen`, or `quadraticspectral`. *kernel* determines the amount of weight given to lagged values when computing the HAC matrix, and `#` denotes the maximum number of lags to use. Many texts refer to the bandwidth of the kernel instead of the number of lags; the bandwidth is equal to the number of lags plus one. If neither `opt` nor `#` is specified, then  $N - 2$  lags are used, where  $N$  is the sample size.

If you specify `wmatrix(hac kernel opt)`, then `ivregress` uses Newey and West's (1994) algorithm for automatically selecting the number of lags to use. Although the authors' Monte Carlo simulations do show that the procedure may result in size distortions of hypothesis tests, the procedure is still useful when little other information is available to help choose the number of lags.

For more on GMM estimation, see [Baum \(2006\)](#); [Baum, Schaffer, and Stillman \(2003, 2007\)](#); [Cameron and Trivedi \(2005\)](#); [Davidson and MacKinnon \(1993\)](#); [Hayashi \(2000\)](#); or [Wooldridge \(2010\)](#). See [Newey and West \(1987\)](#) and [Wang and Wu \(2012\)](#) for an introduction to HAC covariance matrix estimation.

| <code>e(kabsorb)</code>      | number of levels for each absorbed variable            |
| <code>e(dfabsorb)</code>     | adjusted degrees of freedom for each absorbed variable |
| <code>e(ksingle)</code>      | number of singletons for each absorbed variable        |
| Functions                    |                                                        |
| <code>e(sample)</code>       | marks estimation sample                                |

In addition to the above, the following is stored in `r()`:

|                       |                                                                                                                       |
|-----------------------|-----------------------------------------------------------------------------------------------------------------------|
| Matrices              |                                                                                                                       |
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, $p$ -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

## Methods and formulas

Methods and formulas are presented under the following headings:

*Notation*  
*2SLS and LIML estimators*  
*2SLS estimator with absorb() option GMM estimator*

## Notation

Items printed in lowercase and italicized (for example,  $x$ ) are scalars. Items printed in lowercase and boldfaced (for example,  $\mathbf{x}$ ) are vectors. Items printed in uppercase and boldfaced (for example,  $\mathbf{X}$ ) are matrices.

The model is

$$\mathbf{y} = \mathbf{Y}\beta_1 + \mathbf{X}_1\beta_2 + \mathbf{u} = \mathbf{X}\beta + \mathbf{u}$$

$$\mathbf{Y} = \mathbf{X}_1\Pi_1 + \mathbf{X}_2\Pi_2 + \mathbf{V} = \mathbf{Z}\Pi + \mathbf{V}$$

where  $\mathbf{y}$  is an  $N \times 1$  vector of the left-hand-side variable;  $N$  is the sample size;  $\mathbf{Y}$  is an  $N \times p$  matrix of  $p$  endogenous regressors;  $\mathbf{X}_1$  is an  $N \times k_1$  matrix of  $k_1$  included exogenous regressors;  $\mathbf{X}_2$  is an  $N \times k_2$  matrix of  $k_2$  excluded exogenous variables,  $\mathbf{X} = [\mathbf{Y} \ \mathbf{X}_1]$ ,  $\mathbf{Z} = [\mathbf{X}_1 \ \mathbf{X}_2]$ ;  $\mathbf{u}$  is an  $N \times 1$  vector of errors;  $\mathbf{V}$  is an  $N \times p$  matrix of errors;  $\beta = [\beta_1 \ \beta_2]$  is a  $k = (p + k_1) \times 1$  vector of parameters; and  $\Pi$  is a  $(k_1 + k_2) \times p$  vector of parameters. If a constant term is included in the model, then one column of  $\mathbf{X}_1$  contains all ones.

Let  $\mathbf{v}$  be a column vector of weights specified by the user. If no weights are specified,  $\mathbf{v} = \mathbf{1}$ . Let  $\mathbf{w}$  be a column vector of normalized weights. If no weights are specified or if the user specified `fweights` or `weights`,  $\mathbf{w} = \mathbf{v}$ ; otherwise,  $\mathbf{w} = \{\mathbf{v}/(\mathbf{1}'\mathbf{v})\}(\mathbf{1}'\mathbf{1})$ . Let  $\mathbf{D}$  denote the  $N \times N$  matrix with  $\mathbf{w}$  on the main diagonal and zeros elsewhere. If no weights are specified,  $\mathbf{D}$  is the identity matrix.

The weighted number of observations  $n$  is defined as  $\mathbf{1}'\mathbf{w}$ . For `weights`, this is truncated to an integer. The *sum of the weights* is  $\mathbf{1}'\mathbf{v}$ . Define  $c = 1$  if there is a constant in the regression and zero otherwise.

The order condition for identification requires that  $k_2 \geq p$ : the number of excluded exogenous variables must be at least as great as the number of endogenous regressors.

In the following formulas, if weights are specified,  $\mathbf{X}'_1\mathbf{X}_1$ ,  $\mathbf{X}'\mathbf{X}$ ,  $\mathbf{X}'\mathbf{y}$ ,  $\mathbf{y}'\mathbf{y}$ ,  $\mathbf{Z}'\mathbf{Z}$ ,  $\mathbf{Z}'\mathbf{X}$ , and  $\mathbf{Z}'\mathbf{y}$  are replaced with  $\mathbf{X}'_1\mathbf{D}\mathbf{X}_1$ ,  $\mathbf{X}'\mathbf{D}\mathbf{X}$ ,  $\mathbf{X}'\mathbf{D}\mathbf{y}$ ,  $\mathbf{y}'\mathbf{D}\mathbf{y}$ ,  $\mathbf{Z}'\mathbf{D}\mathbf{Z}$ ,  $\mathbf{Z}'\mathbf{D}\mathbf{X}$ , and  $\mathbf{Z}'\mathbf{D}\mathbf{y}$ , respectively. We suppress the  $\mathbf{D}$  below to simplify the notation.

## 2SLS and LIML estimators

Define the  $\kappa$ -class estimator of  $\beta$  as

$$\mathbf{b} = \{\mathbf{X}'(\mathbf{I} - \kappa\mathbf{M}_Z)\mathbf{X}\}^{-1}\mathbf{X}'(\mathbf{I} - \kappa\mathbf{M}_Z)\mathbf{y}$$

where  $\mathbf{M}_Z = \mathbf{I} - \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$ . The 2SLS estimator results from setting  $\kappa = 1$ . The LIML estimator results from selecting  $\kappa$  to be the minimum eigenvalue of  $(\mathbf{Y}'\mathbf{M}_Z\mathbf{Y})^{-1/2}\mathbf{Y}'\mathbf{M}_{\mathbf{X}_1}\mathbf{Y}(\mathbf{Y}'\mathbf{M}_Z\mathbf{Y})^{-1/2}$ , where  $\mathbf{M}_{\mathbf{X}_1} = \mathbf{I} - \mathbf{X}_1(\mathbf{X}_1'\mathbf{X}_1)^{-1}\mathbf{X}_1'$ .

The total sum of squares (TSS) equals  $\mathbf{y}'\mathbf{y}$  if there is no intercept and  $\mathbf{y}'\mathbf{y} - \{(\mathbf{1}'\mathbf{y})^2/n\}$  otherwise. The degrees of freedom is  $n - c$ . The error sum of squares (ESS) is defined as  $\mathbf{y}'\mathbf{y} - 2\mathbf{b}\mathbf{X}'\mathbf{y} + \mathbf{b}'\mathbf{X}'\mathbf{X}\mathbf{b}$ . The model sum of squares (MSS) equals TSS - ESS. The degrees of freedom is  $k - c$ .

The mean squared error,  $s^2$ , is defined as ESS/( $n - k$ ) if `small` is specified and ESS/ $n$  otherwise. The root mean squared error is  $s$ , its square root.

If  $c = 1$  and `small` is not specified, a Wald statistic,  $W$ , of the joint significance of the  $k - 1$  parameters of  $\beta$  except the constant term is calculated;  $W \sim \chi^2(k - 1)$ . If  $c = 1$  and `small` is specified, then an  $F$  statistic is calculated as  $F = W/(k - 1)$ ;  $F \sim F(k - 1, n - k)$ .

The  $R^2$  is defined as  $R^2 = 1 - \text{ESS}/\text{TSS}$ .

The adjusted  $R^2$  is  $R_a^2 = 1 - (1 - R^2)(n - c)/(n - k)$ .

The unadjusted (default) variance estimate is  $\text{Var}(\mathbf{b}) = s^2\{\mathbf{X}'(\mathbf{I} - \kappa\mathbf{M}_Z)\mathbf{X}\}^{-1}$ .

For a general discussion of robust variance estimates in regression, see [A general notation for the robust variance calculation](#) in [R] `regress`. `ivregress` uses the same definitions for terms discussed in [Robust calculation for regress](#) in its robust variance calculation, except for the following.

The vector of scores is given by

$$\mathbf{u}_j = (y_j - \mathbf{x}_j\mathbf{b})\hat{\mathbf{x}}_j$$

where  $\hat{\mathbf{x}}_j' = \mathbf{P}\mathbf{z}_j'$  and  $\mathbf{P} = (\mathbf{X}'\mathbf{Z})(\mathbf{Z}'\mathbf{Z})^{-1}$ . When the formulas in [R] `regress` are applied,  $q_c$  is given by its regressionlike definition. If `small` is not specified, then  $k = 0$  in the formulas given in [R] `regress`.

`ivregress 2sls` and `ivregress liml` also support estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

## 2SLS estimator with absorb() option

When absorbed variables are specified, we must project the dependent variable, instruments, and endogenous variables onto the orthogonal complement of the column space of the absorbed indicator matrices. Using the same notation found in the [Methods and formulas](#) of [R] `areg`, we have  $m_k$  categorical levels for the  $k$ th absorbed variable,  $C_k$ , and an  $N \times m_k$  indicator matrix  $\mathbf{D}_k$ . The orthonormal projection matrix for the  $k$ th variable is  $\mathbf{P}_k = \mathbf{D}_k(\mathbf{D}_k'\mathbf{D}_k)^{-1}\mathbf{D}_k'$ . Thus, the product  $\bar{\mathbf{y}}_k = \mathbf{P}_k\mathbf{y}$  is the projection of the dependent variable onto the column space of  $\mathbf{D}_k$ . That is,  $\bar{\mathbf{y}}_k$  is the  $N \times 1$  vector containing the (repeated) means of  $y_i$  for each level of  $C_k$  in the order that these levels appear in the sample. The product  $(\mathbf{I} - \mathbf{P}_k)\mathbf{y}$  is the vector of the demeaned dependent variable. The same projection (demeaning) is applied to the columns of matrices  $\mathbf{X}_1$ ,  $\mathbf{X}_2$ , and  $\mathbf{Y}$ . The Halperin or Cimmino iterative algorithm loops over the  $h$  absorbed variables computing projections as described in [Methods and formulas](#) of [R] `areg`.

See [Methods and formulas](#) in [R] `areg` for a description of the method used to adjust the degrees of freedom to account for collinearity among absorbed variables when the `dfabsorb` option is specified.

## GMM estimator

We obtain an initial consistent estimate of  $\beta$  by using the 2SLS estimator; see above. Using this estimate of  $\beta$ , we compute the weight matrix  $\mathbf{W}$  and calculate the GMM estimator

$$\mathbf{b}_{\text{GMM}} = \{\mathbf{X}'\mathbf{Z}\mathbf{W}\mathbf{Z}'\mathbf{X}\}^{-1}\mathbf{X}'\mathbf{Z}\mathbf{W}\mathbf{Z}'\mathbf{y}$$

The variance of  $\mathbf{b}_{\text{GMM}}$  is

$$\text{Var}(\mathbf{b}_{\text{GMM}}) = n\{\mathbf{X}'\mathbf{Z}\mathbf{W}\mathbf{Z}'\mathbf{X}\}^{-1}\mathbf{X}'\mathbf{Z}\mathbf{W}\widehat{\mathbf{S}}\mathbf{W}\mathbf{Z}'\mathbf{X}\{\mathbf{X}'\mathbf{Z}\mathbf{W}\mathbf{Z}'\mathbf{X}\}^{-1}$$

$\text{Var}(\mathbf{b}_{\text{GMM}})$  is of the sandwich form **DMD**; see [P] [\\_robust](#). If the user specifies the `small` option, `ivregress` implements a small-sample adjustment by multiplying the VCE by  $N/(N - k)$ .

If `vce(unadjusted)` is specified, then we set  $\widehat{\mathbf{S}} = \mathbf{W}^{-1}$  and the VCE reduces to the “optimal” GMM variance estimator

$$\text{Var}(\beta_{\text{GMM}}) = n\{\mathbf{X}'\mathbf{Z}\mathbf{W}\mathbf{Z}'\mathbf{X}\}^{-1}$$

However, if  $\mathbf{W}^{-1}$  is not a good estimator of  $E(\mathbf{z}_i u_i u_i \mathbf{z}_i')$ , then the optimal GMM estimator is inefficient, and inference based on the optimal variance estimator could be misleading.

$\mathbf{W}$  is calculated using the residuals from the initial 2SLS estimates, whereas  $\mathbf{S}$  is estimated using the residuals based on  $\mathbf{b}_{\text{GMM}}$ . The `wmatrix()` option affects the form of  $\mathbf{W}$ , whereas the `vce()` option affects the form of  $\mathbf{S}$ . Except for different residuals being used, the formulas for  $\mathbf{W}^{-1}$  and  $\mathbf{S}$  are identical, so we focus on estimating  $\mathbf{W}^{-1}$ .

If `wmatrix(unadjusted)` is specified, then

$$\mathbf{W}^{-1} = \frac{s^2}{n} \sum_i \mathbf{z}_i \mathbf{z}_i'$$

where  $s^2 = \sum_i u_i^2/n$ . This weight matrix is appropriate if the errors are homoskedastic.

If `wmatrix(robust)` is specified, then

$$\mathbf{W}^{-1} = \frac{1}{n} \sum_i u_i^2 \mathbf{z}_i \mathbf{z}_i'$$

which is appropriate if the errors are heteroskedastic.

If `wmatrix(cluster clustvar)` is specified, then

$$\mathbf{W}^{-1} = \frac{1}{n} \sum_c \mathbf{q}_c \mathbf{q}_c'$$

where  $c$  indexes clusters,

$$\mathbf{q}_c = \sum_{i \in c_j} u_i \mathbf{z}_i$$

and  $c_j$  denotes the  $j$ th cluster.

If `wmatrix(hac kernel [#])` is specified, then

$$\mathbf{W}^{-1} = \frac{1}{n} \sum_i u_i^2 \mathbf{z}_i \mathbf{z}_i' + \frac{1}{n} \sum_{l=1}^{l=n-1} \sum_{i=l+1}^{i=n} K(l, m) u_i u_{i-l} (\mathbf{z}_i \mathbf{z}_{i-l}' + \mathbf{z}_{i-l} \mathbf{z}_i')$$

where  $m = \#$  if  $\#$  is specified and  $m = n - 2$  otherwise. Define  $z = l/(m + 1)$ . If *kernel* is *nwest*, then

$$K(l, m) = \begin{cases} 1 - z & 0 \leq z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If *kernel* is *gallant*, then

$$K(l, m) = \begin{cases} 1 - 6z^2 + 6z^3 & 0 \leq z \leq 0.5 \\ 2(1 - z)^3 & 0.5 < z \leq 1 \\ 0 & \text{otherwise} \end{cases}$$

If *kernel* is *quadraticspectral*, then

$$K(l, m) = \begin{cases} 1 & z = 0 \\ 3 \{ \sin(\theta)/\theta - \cos(\theta) \} / \theta^2 & \text{otherwise} \end{cases}$$

where  $\theta = 6\pi z/5$ .

If `wmatrix(hac kernel opt)` is specified, then `ivregress` uses Newey and West's (1994) automatic lag-selection algorithm, which proceeds as follows. Define  $\mathbf{h}$  to be a  $(k_1 + k_2) \times 1$  vector containing ones in all rows except for the row corresponding to the constant term (if present); that row contains a zero. Define

$$\begin{aligned} f_i &= (u_i \mathbf{z}_i) \mathbf{h} \\ \hat{\sigma}_j &= \frac{1}{n} \sum_{i=j+1}^n f_i f_{i-j} \quad j = 0, \dots, m^* \\ \hat{s}^{(q)} &= 2 \sum_{j=1}^{m^*} \hat{\sigma}_j j^q \\ \hat{s}^{(0)} &= \hat{\sigma}_0 + 2 \sum_{j=1}^{m^*} \hat{\sigma}_j \\ \hat{\gamma} &= c_\gamma \left\{ \left( \frac{\hat{s}^{(q)}}{\hat{s}^{(0)}} \right)^2 \right\}^{1/2q+1} \\ m &= \hat{\gamma} n^{1/(2q+1)} \end{aligned}$$

where  $q$ ,  $m^*$ , and  $c_\gamma$  depend on the kernel specified:

| Kernel             | $q$ | $m^*$                               | $c_\gamma$ |
|--------------------|-----|-------------------------------------|------------|
| Bartlett           | 1   | $\text{int} \{ 20(T/100)^{2/9} \}$  | 1.1447     |
| Parzen             | 2   | $\text{int} \{ 20(T/100)^{4/25} \}$ | 2.6614     |
| Quadratic spectral | 2   | $\text{int} \{ 20(T/100)^{2/25} \}$ | 1.3221     |

where  $\text{int}(x)$  denotes the integer obtained by truncating  $x$  toward zero. For the Bartlett and Parzen kernels, the optimal lag is  $\min\{\text{int}(m), m^*\}$ . For the quadratic spectral, the optimal lag is  $\min\{m, m^*\}$ .

If `wmatrix(hac kernel opt #)` is specified, then `ivregress` uses  $\#$  instead of 20 in the definition of  $m^*$  above to select the optimal lag.

If center is specified, when computing weight matrices `ivregress` replaces the term  $u_i z_i$  in the formulas above with  $u_i z_i - \bar{u}\bar{z}$ , where  $\bar{u}\bar{z} = \sum_i u_i z_i / N$ .

## Postestimation commands

The following postestimation commands are of special interest after `ivregress`:

| Command                       | Description                                                     |
|-------------------------------|-----------------------------------------------------------------|
| <code>estat endogenous</code> | perform tests of endogeneity                                    |
| <code>estat firststage</code> | report “first-stage” regression statistics                      |
| <code>estat overid</code>     | perform tests of overidentifying restrictions                   |
| <code>estat weakrobust</code> | perform inference robust to weak instruments                    |
| * <code>estat sbknown</code>  | perform tests for a structural break with a known break date    |
| * <code>estat single</code>   | perform tests for a structural break with an unknown break date |

These commands are not appropriate with `svy` estimation results.

\*`estat sbknown` and `estat sbsingle` work only after `ivregress 2s1s`.

The following postestimation commands are also available:

| Command                      | Description                                                                                       |
|------------------------------|---------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                               |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                      |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                         |
| <code>estimates</code>       | cataloging estimation results                                                                     |
| <code>etable</code>          | table of estimation results                                                                       |
| † <code>forecast</code>      | dynamic forecasts and simulations                                                                 |
| † <code>hausman</code>       | Hausman’s specification test                                                                      |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters    |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                           |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters |
| <code>predict</code>         | linear predictions and their SEs, probabilities, etc.                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions              |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                              |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                |

†`forecast` and `hausman` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as linear predictions, residuals, standard errors, probabilities, and expected values.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic]
```

```
predict [type] stub* [if] [in], scores
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

`xb`  $\mathbf{x}_j\mathbf{b}$ , fitted values; the default

`stdp` standard error of the prediction

`stdf` standard error of the forecast

`dresiduals`  $d_{\text{absorbvars}} + e_j = y_j - \mathbf{x}_j\mathbf{b}$

\* `xbd`  $\mathbf{x}_j\mathbf{b} + d_{\text{absorbvars}}$

\* `d`  $d_{\text{absorbvars}}$

`residuals` residuals

† `pr(a,b)`  $\Pr(a < y_j < b)$  under exogeneity and normal errors

† `e(a,b)`  $E(y_j | a < y_j < b)$  under exogeneity and normal errors

† `ystar(a,b)`  $E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\}$  under exogeneity and normal errors

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

†Not allowed if `absorb()` is used at estimation.

`xb`, `stdp`, and `residuals` are the only options allowed with `svy` estimation results.

where *a* and *b* may be numbers or variables; *a* missing (*a* ≥ .) means  $-\infty$ , and *b* missing (*b* ≥ .) means  $+\infty$ ; see [U] 12.2.1 Missing values.

## Options for predict

Main

`xb`, the default, calculates the linear prediction,  $\mathbf{x}_j\mathbf{b}$ .

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. This is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas* in [R] **regress postestimation**.

`dresiduals` calculates  $y_j - \mathbf{x}_j\mathbf{b}$ , which are the residuals plus the effects of the absorbed variables. These are based on the estimated equation when the observed values of the endogenous variables are used—not the projections of the instruments onto the endogenous variables.

`xbd` calculates  $\mathbf{x}_j\mathbf{b} + d_{\text{absorbvar}}$ , which are the fitted values including the individual effects of the absorbed variables.

`d` calculates  $d_{\text{absorbvar}}$ , the sum of individual coefficients for the absorbed variables.

`residuals` calculates the residuals, that is,  $y_j - (\mathbf{x}_j\mathbf{b} + d_{\text{absorbvar}})$ .

`pr(a,b)` calculates  $\Pr(a < \mathbf{x}_j\mathbf{b} + u_j < b)$ , the probability that  $y_j|\mathbf{x}_j$  would be observed in the interval  $(a,b)$  under exogeneity and assuming errors are normally distributed.

$a$  and  $b$  may be specified as numbers or variable names;  $lb$  and  $ub$  are variable names;

`pr(20,30)` calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < 30)$ ;

`pr(lb,ub)` calculates  $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < ub)$ ; and

`pr(20,ub)` calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$ .

$a$  missing ( $a \geq .$ ) means  $-\infty$ ; `pr(. ,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$ ;

`pr(lb,30)` calculates  $\Pr(-\infty < \mathbf{x}_j\mathbf{b} + u_j < 30)$  in observations for which  $lb \geq .$

and calculates  $\Pr(lb < \mathbf{x}_j\mathbf{b} + u_j < 30)$  elsewhere.

$b$  missing ( $b \geq .$ ) means  $+\infty$ ; `pr(20, .)` calculates  $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$ ;

`pr(20,ub)` calculates  $\Pr(+\infty > \mathbf{x}_j\mathbf{b} + u_j > 20)$  in observations for which  $ub \geq .$

and calculates  $\Pr(20 < \mathbf{x}_j\mathbf{b} + u_j < ub)$  elsewhere.

`e(a,b)` calculates  $E(\mathbf{x}_j\mathbf{b} + u_j | a < \mathbf{x}_j\mathbf{b} + u_j < b)$ , the expected value of  $y_j|\mathbf{x}_j$  conditional on  $y_j|\mathbf{x}_j$  being in the interval  $(a,b)$ , meaning that  $y_j|\mathbf{x}_j$  is truncated.  $a$  and  $b$  are specified as they are for `pr()`. Exogeneity and normally distributed errors are assumed.

`ystar(a,b)` calculates  $E(y_j^*)$ , where  $y_j^* = a$  if  $\mathbf{x}_j\mathbf{b} + u_j \leq a$ ,  $y_j^* = b$  if  $\mathbf{x}_j\mathbf{b} + u_j \geq b$ , and  $y_j^* = \mathbf{x}_j\mathbf{b} + u_j$  otherwise, meaning that  $y_j^*$  is censored.  $a$  and  $b$  are specified as they are for `pr()`. Exogeneity and normally distributed errors are assumed.

`scores` calculates the scores for the model. A new score variable is created for each endogenous regressor, as well as an equation-level score that applies to all exogenous variables and constant term (if present). `scores` is not allowed if the `absorb()` option is used at estimation.

## margins

### Description for margins

`margins` estimates margins of response for linear predictions, probabilities, and expected values.

### Menu for margins

Statistics > Postestimation

### Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>                      | Description                                                                    |
|---------------------------------------|--------------------------------------------------------------------------------|
| <code>xb</code>                       | linear prediction; the default                                                 |
| <code>stdp</code>                     | not allowed with <code>margins</code>                                          |
| <code>stdf</code>                     | not allowed with <code>margins</code>                                          |
| <code>dresiduals</code>               | not allowed with <code>margins</code>                                          |
| <code>xbd</code>                      | not allowed with <code>margins</code>                                          |
| <code>d</code>                        | not allowed with <code>margins</code>                                          |
| <code>residuals</code>                | not allowed with <code>margins</code>                                          |
| <code>pr(<i>a</i>,<i>b</i>)</code>    | $\Pr(a < y_j < b)$ under exogeneity and normal errors                          |
| <code>e(<i>a</i>,<i>b</i>)</code>     | $E(y_j   a < y_j < b)$ under exogeneity and normal errors                      |
| <code>ystar(<i>a</i>,<i>b</i>)</code> | $E(y_j^*, y_j^* = \max\{a, \min(y_j, b)\})$ under exogeneity and normal errors |

Statistics not allowed with `margins` are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## estat

### Description for estat

`estat endogenous` performs tests to determine whether endogenous regressors in the model are in fact exogenous. After GMM estimation, the  $C$  (difference-in-Sargan) statistic is reported. After 2SLS estimation with an unadjusted VCE, the Durbin (1954) and Wu–Hausman (Wu 1974; Hausman 1978) statistics are reported. After 2SLS estimation with a robust VCE, Wooldridge’s (1995) robust score test and a robust regression-based test are reported. In all cases, if the test statistic is significant, then the variables being tested must be treated as endogenous. `estat endogenous` is not available after LIML estimation.

`estat firststage` reports various statistics that measure the relevance of the excluded exogenous variables. By default, which statistics are reported depends on whether the equation has one or more than one endogenous regressor.

`estat overid` performs tests of overidentifying restrictions. If the 2SLS estimator was used, Sargan’s (1958) and Basman’s (1960)  $\chi^2$  tests are reported, as is Wooldridge’s (1995) robust score test; if the LIML estimator was used, Anderson and Rubin’s (1950)  $\chi^2$  test and Basman’s  $F$  test are reported; and if the GMM estimator was used, Hansen’s (1982)  $J$  statistic  $\chi^2$  test is reported. In all of these cases, a rejection of the test indicates that the instruments may not be valid.

`estat weakrobust` performs hypothesis tests on the coefficients of endogenous regressors that are robust to weak instruments. For just-identified models, the Anderson–Rubin (1949) test is reported. For overidentified models, if a homoskedastic VCE was used in estimation, the conditional likelihood-ratio (CLR) test of Moreira (2003) is reported. If a heteroskedastic or cluster–robust VCE was used instead, an appropriate generalization of the CLR test is used (see Finlay and Magnusson [2009]). When there is only one endogenous regressor, the confidence intervals associated with any of these tests can be requested.

`collect` is allowed with `estat endogenous`, `estat firststage`, `estat overid`, and `estat weakrobust`; see [U] 11.1.10 Prefix commands.

## Options for estat

Options for `estat` are presented under the following headings:

[Options for estat endogenous](#)

[Options for estat firststage](#)

[Options for estat overid](#)

[Options for estat weakrobust](#)

## Options for estat endogenous

`lags(#)` specifies the number of lags to use for prewhitening when computing the heteroskedasticity- and autocorrelation-consistent (HAC) version of the score test of endogeneity. Specifying `lags(0)` requests no prewhitening. This option is valid only when the model was fit via 2SLS and a HAC covariance matrix was requested when the model was fit. The default is `lags(1)`.

`forceweights` requests that the tests of endogeneity be computed even though `aweight`s, `pweight`s, or `iweight`s were used in the previous estimation. By default, these tests are conducted only after unweighted or frequency-weighted estimation. The reported critical values may be inappropriate for weighted data, so the user must determine whether the critical values are appropriate for a given application.

`forcenonrobust` requests that the Durbin and Wu–Hausman tests be performed after 2SLS estimation even though a robust VCE was used at estimation time. This option is available only if the model was fit by 2SLS.

## Options for estat firststage

`all` requests that all first-stage goodness-of-fit statistics be reported regardless of whether the model contains one or more endogenous regressors. By default, if the model contains one endogenous regressor, then the first-stage  $R^2$ , adjusted  $R^2$ , partial  $R^2$ , and  $F$  statistics are reported, whereas if the model contains multiple endogenous regressors, then Shea's partial  $R^2$  and adjusted partial  $R^2$  are reported instead.

`forcenonrobust` requests that the minimum eigenvalue statistic and its critical values be reported even though a robust VCE was used at estimation time. The reported critical values assume that the errors are independent and identically distributed (i.i.d.) normal, so the user must determine whether the critical values are appropriate for a given application.

## Options for `estat overid`

`lags(#)` specifies the number of lags to use for prewhitening when computing the heteroskedasticity- and autocorrelation-consistent (HAC) version of the score test of overidentifying restrictions. Specifying `lags(0)` requests no prewhitening. This option is valid only when the model was fit via 2SLS and a HAC covariance matrix was requested when the model was fit. The default is `lags(1)`.

`forceweights` requests that the tests of overidentifying restrictions be computed even though `aweights`, `pweights`, or `iweights` were used in the previous estimation. By default, these tests are conducted only after unweighted or frequency-weighted estimation. The reported critical values may be inappropriate for weighted data, so the user must determine whether the critical values are appropriate for a given application.

`forcenonrobust` requests that the Sargan and Basman tests of overidentifying restrictions be performed after 2SLS or LIML estimation even though a robust VCE was used at estimation time. These tests assume that the errors are i.i.d. normal, so the user must determine whether the critical values are appropriate for a given application.

## Options for `estat weakrobust`

`betanull(null_spec)` specifies the null hypothesis of the test on the coefficients of the endogenous regressors. By default, the null hypothesis is that the coefficients of all endogenous regressors are zero. The null hypothesis can be specified using `numlist`, a list of equalities, or a matrix. When using `numlist`, you must specify the null values for all endogenous regressors in the order given in the estimation command and specify the `copy` suboption if there is more than one endogenous regressor. When you use a list of equalities or a matrix, null values are set to zero for endogenous regressors you did not specify. When you use a matrix, null values are assigned to coefficients by matrix column names.

`null_spec` is one of

`# [#... , copy]`

`varname = # [varname = # [...]] [, skip]`

`matname [ , skip copy]`

`skip` specifies that any variables that are not endogenous regressors in the model be ignored. The default action is to issue an error message.

`copy` specifies that the list of null values be assigned into the null hypothesis by position rather than by name.

`ar` requests that an Anderson–Rubin test be performed. The associated confidence interval of the test can be requested with the `ci` option. By default, the Anderson–Rubin test is performed when the model is just identified. If both `ar` and `clr` are specified, both tests are performed.

`clr` requests that a CLR test be performed. The associated confidence interval of the test can be requested with the `ci` option. By default, a CLR test is performed when the model is overidentified. If both `ar` and `clr` are specified, both tests are performed.

- `ci` requests that a confidence interval be returned instead of a test statistic and a  $p$ -value. This applies to all tests specified by the user. Option `ci` is available only when there is a single endogenous regressor.
- `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.
- `reps(#)` specifies the number of replications to use in simulating critical values when  $p$ -values cannot be computed analytically. The default is `reps(25000)`.
- `rseed(#)` sets the random-number seed. This option can be used to reproduce results for simulating critical values when  $p$ -values cannot be computed analytically. `rseed(#)` is equivalent to typing `set seed #` prior to calling `estat weakrobust`; see [R] set seed.
- `bound(#min #max)` specifies the lower (`#min`) and the upper bound (`#max`) for the grid used to approximate confidence intervals when they cannot be computed analytically. The specified bounds will be the starting bounds for the adaptive grid expansion procedure or, if `noadaptgrid` is specified, the fixed bounds of the grid. By default, the lower bound is set to five standard errors below the coefficient estimated by `ivregress`, and the upper bound is five standard errors above.
- `ngrid(#)` specifies the starting number of gridpoints for approximating confidence intervals. The default is `ngrid(500)`. Higher values will increase computation time but improve precision, which may be helpful when the confidence interval is wide. If `noadaptgrid` is specified, `ngrid()` specifies the fixed number of gridpoints.
- `noadaptgrid` requests that the default method for computing confidence intervals, where the grid is adaptively expanded, be turned off and the interval be estimated with a fixed grid. `noadaptgrid` is equivalent to specifying `iterate(0)`.
- `log` and `nolog` specify whether to display the iteration log showing the progress of the adaptive gridding procedure. The iteration log is displayed by default unless you used `set iterlog off` to suppress it; see `set iterlog` in [R] set iter.
- `iterate(#)` specifies the maximum number of iterations for the adaptive grid expansion procedure. Each iteration expands the grid by half the width of the starting bounds in each direction, and the procedure stops when the maximum number of iterations is reached or when the confidence interval has finite endpoints and was unchanged by the most recent expansion. The default is `iterate(20)`.

## Remarks and examples

Remarks are presented under the following headings:

*estat endogenous*  
*estat firststage*  
*estat overid*  
*estat weakrobust*

## estat endogenous

A natural question to ask is whether a variable presumed to be endogenous in the previously fit model could instead be treated as exogenous. If the endogenous regressors are in fact exogenous, then the OLS estimator is more efficient; and depending on the strength of the instruments and other factors, the sacrifice in efficiency by using an instrumental-variables estimator can be significant. Thus, unless an instrumental-variables estimator is really needed, OLS should be used instead. `estat endogenous` provides several tests of endogeneity after 2SLS and GMM estimation.

## ▷ Example 1

In [example 1](#) of [R] `ivregress`, we fit a model of the average rental rate for housing in a state as a function of the percentage of the population living in urban areas and the average value of houses. We treated `hshgval` as endogenous because unanticipated shocks that affect rental rates probably affect house prices as well. We used family income and region dummies as additional instruments for `hshgval`. Here we test whether we could treat `hshgval` as exogenous.

```
. use https://www.stata-press.com/data/r19/hshg
(1980 Census housing data)
. ivregress 2sls rent pcturban (hshgval = faminc i.region)
(output omitted)
. estat endogenous
Tests of endogeneity
H0: Variables are exogenous
Durbin (score) chi2(1) = 12.8473 (p = 0.0003)
Wu-Hausman F(1,46) = 15.9067 (p = 0.0002)
```

Because we did not specify any variable names after the `estat endogenous` command, Stata by default tested all the endogenous regressors (namely, `hshgval`) in our model. The null hypothesis of the Durbin and Wu–Hausman tests is that the variable under consideration can be treated as exogenous. Here both test statistics are highly significant, so we reject the null of exogeneity; we must continue to treat `hshgval` as endogenous.

◀

The difference between the Durbin and Wu–Hausman tests of endogeneity is that the former uses an estimate of the error term’s variance based on the model assuming the variables being tested are exogenous, while the latter uses an estimate of the error variance based on the model assuming the variables being tested are endogenous. Under the null hypothesis that the variables being tested are exogenous, both estimates of the error variance are consistent. What we label the Wu–Hausman statistic is Wu’s (1974) “ $T_2$ ” statistic, which Hausman (1978) showed can be calculated very easily via linear regression. Baum, Schaffer, and Stillman (2003, 2007) provide a lucid discussion of these tests.

When you fit a model with multiple endogenous regressors, you can test the exogeneity of a subset of the regressors while continuing to treat the others as endogenous. For example, say you have three endogenous regressors,  $y_1$ ,  $y_2$ , and  $y_3$ , and you fit your model by typing

```
. ivregress depvar ... (y1 y2 y3 = ...)
```

Suppose you are confident that  $y_1$  must be treated as endogenous, but you are undecided about  $y_2$  and  $y_3$ . To test whether  $y_2$  and  $y_3$  can be treated as exogenous, you would type

```
. estat endogenous y2 y3
```

The Durbin and Wu–Hausman tests assume that the error term is i.i.d. Therefore, if you requested a robust VCE at estimation time, `estat endogenous` will instead report Wooldridge’s (1995) score test and a regression-based test of exogeneity. Both these tests can tolerate heteroskedastic and autocorrelated errors, while only the regression-based test is amenable to clustering.

## ▷ Example 2

We refit our housing model, requesting robust standard errors, and then test the exogeneity of `hsngval`:

```
. use https://www.stata-press.com/data/r19/hsng
(1980 Census housing data)
. ivregress 2sls rent pcturban (hsngval = faminc i.region), vce(robust)
(output omitted)
. estat endogenous
Tests of endogeneity
H0: Variables are exogenous
Robust score chi2(1) = 2.10428 (p = 0.1469)
Robust regression F(1,46) = 4.31101 (p = 0.0435)
```

Wooldridge’s score test does not reject the null hypothesis that `hsngval` is exogenous at conventional significance levels ( $p = 0.1469$ ). However, the regression-based test does reject the null hypothesis at the 5% significance level ( $p = 0.0435$ ). Typically, these two tests yield the same conclusion; the fact that our dataset has only 50 observations could be contributing to the discrepancy. Here we would be inclined to continue to treat `hsngval` as endogenous. Even if `hsngval` is exogenous, the 2SLS estimates are still consistent. On the other hand, if `hsngval` is in fact endogenous, the OLS estimates would not be consistent. Moreover, as we will see in our discussion of the `estat overid` command, our additional instruments may be invalid. To test whether an endogenous variable can be treated as exogenous, we must have a valid set of instruments to use to fit the model in the first place!

◀

Unlike the Durbin and Wu–Hausman tests, Wooldridge’s score and the regression-based tests do not allow you to test a subset of the endogenous regressors in the model; you can test only whether all the endogenous regressors are in fact exogenous.

After GMM estimation, `estat endogenous` calculates what Hayashi (2000, 220) calls the  $C$  statistic, also known as the difference-in-Sargan statistic. The  $C$  statistic can be made robust to heteroskedasticity, autocorrelation, and clustering; and the version reported by `estat endogenous` is determined by the weight matrix requested via the `wmatrix()` option used when fitting the model with `ivregress`. Additionally, the test can be used to determine the exogeneity of a subset of the endogenous regressors, regardless of the type of weight matrix used.

If you fit your model using the LIML estimator, you can use the `hausman` command to carry out a traditional Hausman (1978) test between the OLS and LIML estimates.

## estat firststage

For an excluded exogenous variable to be a valid instrument, it must be sufficiently correlated with the included endogenous regressors but uncorrelated with the error term. In recent decades, researchers have paid considerable attention to the issue of instruments that are only weakly correlated with the endogenous regressors. In such cases, the usual 2SLS, GMM, and LIML estimators are biased toward the OLS estimator, and inference based on the standard errors reported by, for example, `ivregress` can be severely misleading. For more information on the theory behind instrumental-variables estimation with weak instruments, see Nelson and Startz (1990); Staiger and Stock (1997); Hahn and Hausman (2003); the survey article by Stock, Wright, and Yogo (2002); and Angrist and Pischke (2009, chap. 4).

When the instruments are only weakly correlated with the endogenous regressors, some Monte Carlo evidence suggests that the LIML estimator performs better than the 2SLS and GMM estimators; see, for example, [Poi \(2006\)](#) and [Stock, Wright, and Yogo \(2002\)](#) (and the papers cited therein). On the other hand, the LIML estimator often results in confidence intervals that are somewhat larger than those from the 2SLS estimator.

Moreover, using more instruments is not a solution, because the biases of instrumental-variables estimators increase with the number of instruments. See [Hahn and Hausman \(2003\)](#).

`estat firststage` produces several statistics for judging the explanatory power of the instruments and is most easily explained with examples.

### ▷ Example 3

Again building on the model fit in [example 1](#) of [\[R\] ivregress](#), we now explore the degree of correlation between the additional instruments `faminc`, `2.region`, `3.region`, and `4.region` and the endogenous regressor `hsngval`:

```
. use https://www.stata-press.com/data/r19/hsng
(1980 Census housing data)
. ivregress 2sls rent pcturban (hsngval = faminc i.region)
(output omitted)
. estat firststage
```

First-stage regression summary statistics

| Variable | R-sq.  | Adjusted R-sq. | Partial R-sq. | F(4,44) | Prob > F |
|----------|--------|----------------|---------------|---------|----------|
| hsngval  | 0.6908 | 0.6557         | 0.5473        | 13.2978 | 0.0000   |

Minimum eigenvalue statistic = 13.2978

|                          |                             |   |
|--------------------------|-----------------------------|---|
| Critical Values          | # of endogenous regressors: | 1 |
| H0: Instruments are weak | # of excluded instruments:  | 4 |

|                                   | 5%    | 10%   | 20%   | 30%  |
|-----------------------------------|-------|-------|-------|------|
| 2SLS relative bias                | 16.85 | 10.27 | 6.71  | 5.34 |
| 2SLS size of nominal 5% Wald test | 24.58 | 13.96 | 10.26 | 8.31 |
| LIML size of nominal 5% Wald test | 5.44  | 3.87  | 3.30  | 2.98 |

To understand these results, recall that the first-stage regression is

$$\text{hsngval}_i = \pi_0 + \pi_1 \text{pcturban}_i + \pi_2 \text{faminc} + \pi_3 \text{2.region} + \pi_4 \text{3.region} + \pi_5 \text{4.region} + v_i$$

where  $v_i$  is an error term. The column marked “R-sq.” is the simple  $R^2$  from fitting the first-stage regression by OLS, and the column marked “Adjusted R-sq.” is the adjusted  $R^2$  from that regression. Higher values purportedly indicate stronger instruments, and instrumental-variables estimators exhibit less bias when the instruments are strongly correlated with the endogenous variable.

Looking at just the  $R^2$  and adjusted  $R^2$  can be misleading, however. If `hsngval` were strongly correlated with the included exogenous variable `pcturban` but only weakly correlated with the additional instruments, then these statistics could be large even though a weak-instrument problem is present.

The partial  $R^2$  statistic measures the correlation between `hsgnval` and the additional instruments after *partialing out* the effect of `pcturban`. Unlike the  $R^2$  and adjusted  $R^2$  statistics, the partial  $R^2$  statistic will not be inflated because of strong correlation between `hsgnval` and `pcturban`. Bound, Jaeger, and Baker (1995) and others have promoted using this statistic.

The column marked “F(4, 44)” is an  $F$  statistic for the joint significance of  $\pi_2$ ,  $\pi_3$ ,  $\pi_4$ , and  $\pi_5$ , the coefficients on the additional instruments. Its  $p$ -value is listed in the column marked “Prob > F”. If the  $F$  statistic is not significant, then the additional instruments have no significant explanatory power for `hsgnval` after controlling for the effect of `pcturban`. However, Hall, Rudebusch, and Wilcox (1996) used Monte Carlo simulation to show that simply having an  $F$  statistic that is significant at the typical 5% or 10% level is not sufficient. Stock, Wright, and Yogo (2002) suggest that the  $F$  statistic should exceed 10 for inference based on the 2SLS estimator to be reliable when there is one endogenous regressor.

`estat firststage` also presents the Cragg and Donald (1993) minimum eigenvalue statistic as a further test of weak instruments. Stock and Yogo (2005) discuss two characterizations of weak instruments: first, weak instruments cause instrumental-variables estimators to be biased; second, hypothesis tests of parameters estimated by instrumental-variables estimators may suffer from severe size distortions. The test statistic in our example is 13.30, which is identical to the  $F$  statistic just discussed because our model contains one endogenous regressor.

The null hypothesis of each of Stock and Yogo’s tests is that the set of instruments is weak. To perform these tests, we must first choose either the largest relative bias of the 2SLS estimator we are willing to tolerate or the largest rejection rate of a nominal 5% Wald test we are willing to tolerate. If the test statistic exceeds the critical value, we can conclude that our instruments are not weak.

The row marked “2SLS relative bias” contains critical values for the test that the instruments are weak based on the bias of the 2SLS estimator *relative to* the bias of the OLS estimator. For example, from past experience we might know that the OLS estimate of a parameter  $\beta$  may be 50% too high. Saying that we are willing to tolerate a 10% relative bias means that we are willing to tolerate a bias of the 2SLS estimator no greater than 5% (that is, 10% of 50%). In our rental rate model, if we are willing to tolerate a 10% relative bias, then we can conclude that our instruments are not weak because the test statistic of 13.30 exceeds the critical value of 10.27. However, if we were willing to tolerate only a relative bias of 5%, we would conclude that our instruments are weak because  $13.30 < 16.85$ .

The rows marked “2SLS Size of nominal 5% Wald test” and “LIML Size of nominal 5% Wald test” contain critical values pertaining to Stock and Yogo’s (2005) second characterization of weak instruments. This characterization defines a set of instruments to be weak if a Wald test at the 5% level can have an actual rejection rate of no more than 10%, 15%, 20%, or 25%. Using the current example, suppose that we are willing to accept a rejection rate of at most 10%. Because  $13.30 < 24.58$ , we cannot reject the null hypothesis of weak instruments. On the other hand, if we use the LIML estimator instead, then we can reject the null hypothesis because  $13.30 > 5.44$ .

◀

## □ Technical note

Stock and Yogo (2005) tabulated critical values for 2SLS relative biases of 5%, 10%, 20%, and 30% for models with 1, 2, or 3 endogenous regressors and between 3 and 30 excluded exogenous variables (instruments). They also provide critical values for worst-case rejection rates of 5%, 10%, 20%, and 25% for nominal 5% Wald tests of the endogenous regressors with 1 or 2 endogenous regressors and between 1 and 30 instruments. If the model previously fit by `ivregress` has more instruments or endogenous regressors than these limits, the critical values are not shown. Stock and Yogo did not consider GMM estimators.

□

When the model being fit contains more than one endogenous regressor, the  $R^2$  and  $F$  statistics described above can overstate the relevance of the excluded instruments. Suppose that there are two endogenous regressors,  $Y_1$  and  $Y_2$ , and that there are two additional instruments,  $z_1$  and  $z_2$ . Say that  $z_1$  is highly correlated with both  $Y_1$  and  $Y_2$  but  $z_2$  is not correlated with either  $Y_1$  or  $Y_2$ . Then, the first-stage regression of  $Y_1$  on  $z_1$  and  $z_2$  (along with the included exogenous variables) will produce large  $R^2$  and  $F$  statistics, as will the regression of  $Y_2$  on  $z_1$ ,  $z_2$ , and the included exogenous variables. Nevertheless, the lack of correlation between  $z_2$  and  $Y_1$  and  $Y_2$  is problematic. Here, although the order condition indicates that the model is just identified (the number of excluded instruments equals the number of endogenous regressors), the irrelevance of  $z_2$  implies that the model is in fact not identified. Even if the model is overidentified, including irrelevant instruments can adversely affect the properties of instrumental-variables estimators, because their biases increase as the number of instruments increases.

#### ▷ Example 4

`estat firststage` presents different statistics when the model contains multiple endogenous regressors. For illustration, we refit our model of rental rates, assuming that both `hsngval` and `faminc` are endogenously determined. We use `i.region` along with `popden`, a measure of population density, as additional instruments.

```
. ivregress 2sls rent pcturban (hsngval faminc = i.region popden)
(output omitted)
```

```
. estat firststage
```

Shea's partial R-squared

| Variable | Shea's partial R-sq. | Shea's adj. partial R-sq. |
|----------|----------------------|---------------------------|
| hsngval  | 0.3477               | 0.2897                    |
| faminc   | 0.1893               | 0.1173                    |

Minimum eigenvalue statistic = 2.51666

|                          |                             |   |
|--------------------------|-----------------------------|---|
| Critical Values          | # of endogenous regressors: | 2 |
| H0: Instruments are weak | # of excluded instruments:  | 4 |

|                                   | 5%    | 10%  | 20%  | 30%  |
|-----------------------------------|-------|------|------|------|
| 2SLS relative bias                | 11.04 | 7.56 | 5.57 | 4.73 |
| 2SLS size of nominal 5% Wald test | 16.87 | 9.93 | 7.54 | 6.28 |
| LIML size of nominal 5% Wald test | 4.72  | 3.39 | 2.99 | 2.79 |

Consider the endogenous regressor `hsngval`. Part of its variation is attributable to its correlation with the other regressors `pcturban` and `faminc`. The other component of `hsngval`'s variation is peculiar to it and orthogonal to the variation in the other regressors. Similarly, we can think of the instruments as predicting the variation in `hsngval` in two ways, one stemming from the fact that the predicted values of `hsngval` are correlated with the predicted values of the other regressors and one from the variation in the predicted values of `hsngval` that is orthogonal to the variation in the predicted values of the other regressors.

What really matters for instrumental-variables estimation is whether the component of `hsngval` that is orthogonal to the other regressors can be explained by the component of the predicted value of `hsngval` that is orthogonal to the predicted values of the other regressors in the model. Shea's (1997) partial

$R^2$  statistic measures this correlation. Because the bias of instrumental-variables estimators increases as more instruments are used, Shea's adjusted partial  $R^2$  statistic is often used instead, as it makes a degrees-of-freedom adjustment for the number of instruments, analogous to the adjusted  $R^2$  measure used in OLS regression. Although what constitutes a "low" value for Shea's partial  $R^2$  depends on the specifics of the model being fit and the data used, these results, taken in isolation, do not strike us as being a particular cause for concern.

However, with this specification the minimum eigenvalue statistic is low. We cannot reject the null hypothesis of weak instruments for either of the characterizations we have discussed.

◀

By default, `estat firststage` determines which statistics to present based on the number of endogenous regressors in the model previously fit. However, you can specify the `all` option to obtain all the statistics.

### □ Technical note

If the previous estimation was conducted using `aweight`s, `pweight`s, or `iweight`s, then the first-stage regression summary statistics are computed using those weights. However, in these cases the minimum eigenvalue statistic and its critical values are not available.

If the previous estimation included a robust VCE, then the first-stage  $F$  statistic is based on a robust VCE as well; for example, if you fit your model with a HAC VCE using the Bartlett kernel and four lags, then the  $F$  statistic reported is based on regression results using a HAC VCE using the Bartlett kernel and four lags. By default, the minimum eigenvalue statistic and its critical values are not displayed. You can use the `forcenonrobust` option to obtain them in these cases; the minimum eigenvalue statistic is computed using the weights, though the critical values reported may not be appropriate.

□

### estat overid

In addition to the requirement that instrumental variables be correlated with the endogenous regressors, the instruments must also be uncorrelated with the structural error term. If the model is overidentified, meaning that the number of additional instruments exceeds the number of endogenous regressors, then we can test whether the instruments are uncorrelated with the error term. If the model is just identified, then we cannot perform a test of overidentifying restrictions.

The estimator you used to fit the model determines which tests of overidentifying restrictions `estat overid` reports. If you used the 2SLS estimator without a robust VCE, `estat overid` reports Sargan's (1958) and Basmann's (1960)  $\chi^2$  tests. If you used the 2SLS estimator and requested a robust VCE, Wooldridge's robust score test of overidentifying restrictions is performed instead; without a robust VCE, Wooldridge's test statistic is identical to Sargan's test statistic. If you used the LIML estimator, `estat overid` reports the Anderson–Rubin (1950) likelihood-ratio test and Basmann's (1960)  $F$  test. `estat overid` reports Hansen's (1982)  $J$  statistic if you used the GMM estimator. Davidson and MacKinnon (1993, 235–236) give a particularly clear explanation of the intuition behind tests of overidentifying restrictions. Also see Judge et al. (1985, 614–616) for a summary of tests of overidentifying restrictions for the 2SLS and LIML estimators.

Tests of overidentifying restrictions actually test two different things simultaneously. One, as we have discussed, is whether the instruments are uncorrelated with the error term. The other is that the equation is misspecified and that one or more of the excluded exogenous variables should in fact be included in the structural equation. Thus, a significant test statistic could represent either an invalid instrument or an incorrectly specified structural equation.

## ▶ Example 5

Here we refit the model that treated just `hsgnval` as endogenous using 2SLS, and then we perform tests of overidentifying restrictions:

```
. ivregress 2sls rent pcturban (hsgnval = faminc i.region)
(output omitted)
. estat overid
Tests of overidentifying restrictions:
Sargan (score) chi2(3) = 11.2877 (p = 0.0103)
Basman chi2(3) = 12.8294 (p = 0.0050)
```

Both test statistics are significant at the 5% test level, which means that either one or more of our instruments are invalid or that our structural model is specified incorrectly.

One possibility is that the error term in our structural model is heteroskedastic. Both Sargan's and Basman's tests assume that the errors are i.i.d.; if the errors are not i.i.d., then these tests are not valid. Here we refit the model by requesting heteroskedasticity-robust standard errors, and then we use `estat overid` to obtain Wooldridge's score test of overidentifying restrictions, which is robust to heteroskedasticity.

```
. ivregress 2sls rent pcturban (hsgnval = faminc i.region), vce(robust)
(output omitted)
. estat overid
Test of overidentifying restrictions:
Score chi2(3) = 6.8364 (p = 0.0773)
```

Here we no longer reject the null hypothesis that our instruments are valid at the 5% significance level, though we do reject the null at the 10% level. You can verify that the robust standard error on the coefficient for `hsgnval` is more than twice as large as its nonrobust counterpart and that the robust standard error for `pcturban` is nearly 50% larger.

◀

## □ Technical note

The test statistic for the test of overidentifying restrictions performed after GMM estimation is simply the sample size times the value of the objective function  $Q(\beta_1, \beta_2)$  defined in (5) of [R] `ivregress`, evaluated at the GMM parameter estimates. If the weight matrix  $\mathbf{W}$  is optimal, meaning that  $\mathbf{W} = \text{Var}(\mathbf{z}_i u_i)$ , then  $Q(\beta_1, \beta_2) \overset{A}{\sim} \chi^2(q)$ , where  $q$  is the number of overidentifying restrictions. However, if the estimated  $\mathbf{W}$  is not optimal, then the test statistic will not have an asymptotic  $\chi^2$  distribution.

Like the Sargan and Basman tests of overidentifying restrictions for the 2SLS estimator, the Anderson–Rubin and Basman tests after LIML estimation are predicated on the errors' being i.i.d. If the previous LIML results were reported with robust standard errors, then `estat overid` by default issues an error message and refuses to report the Anderson–Rubin and Basman test statistics. You can use the `forcenonrobust` option to override this behavior. You can also use `forcenonrobust` to obtain the Sargan and Basman test statistics after 2SLS estimation with robust standard errors.

□

By default, `estat overid` issues an error message if the previous estimation was conducted using `aweight`s, `pweight`s, or `iweight`s. You can use the `forceweights` option to override this behavior, though the test statistics may no longer have the expected  $\chi^2$  distributions.

## estat weakrobust

Instrumental-variables methods require that the instruments be correlated with the endogenous regressors. In principle, this is a low bar: even instruments only weakly correlated with the endogenous regressors allow for valid asymptotic inference using standard instrumental-variables methods. But weak instruments can lead to misleading inference in practice, even in relatively large samples. This is especially the case when models are overidentified or there is a high degree of endogeneity.

When instruments are weak, first-stage coefficients are small relative to the variance of their estimates. This causes the distribution of instrumental-variables estimators to be highly nonnormal and thus poorly approximated by standard inference methods. (See [Andrews, Stock, and Sun \[2019\]](#).)

The linear instrumental-variables model fit by `ivregress` is written in matrix form as

$$\begin{aligned} \mathbf{y} &= \mathbf{Y}\beta_1 + \mathbf{X}_1\beta_2 + \mathbf{u} \\ \mathbf{Y} &= \mathbf{X}_1\Pi_1 + \mathbf{X}_2\Pi_2 + \mathbf{V} \end{aligned}$$

where  $\mathbf{y}$  is a vector with the values of the dependent variable in the sample,  $\mathbf{Y}$  is a matrix of endogenous regressors,  $\mathbf{X}_1$  is a matrix of included exogenous regressors, and  $\mathbf{X}_2$  is a matrix of excluded exogenous regressors. The first equation is referred to as the structural equation, and the second equation is referred to as the first-stage equation. By substituting the endogenous regressors  $\mathbf{Y}$  into the structural equation and reparameterizing, we derive the reduced-form equation

$$\mathbf{y} = \mathbf{X}_1\delta_1 + \mathbf{X}_2\delta_2 + \epsilon$$

where  $\delta_1 \equiv \Pi_1\beta_1 + \beta_2$  and  $\delta_2 \equiv \Pi_2\beta_1$ .

The principle of the tests performed by `estat weakrobust` is that the reduced-form and first-stage equations are free of endogeneity. The estimates of  $\delta_1$ ,  $\delta_2$ ,  $\Pi_1$ , and  $\Pi_2$  can be tested for consistency with a null hypothesis about  $\beta_1$ , our parameter of interest. (In practice, the exogenous covariates  $\mathbf{X}_2$  are partialled out for simplicity.) `estat weakrobust` performs tests of the form  $\beta_1 = \mathbf{r}_1$ , where  $\mathbf{r}_1$  is a constant vector of the same dimension as  $\beta_1$ .

When the model is just identified, meaning there are no more instruments than there are endogenous regressors, the test of [Anderson and Rubin \(1949\)](#), or the associated confidence interval, is reported by default. When the model has been fit with a heteroskedastic, cluster-robust, or HAC VCE, an appropriate version of the Anderson–Rubin test or confidence interval is reported. In all cases, the Anderson–Rubin test statistic takes on a  $\chi^2$  distribution, and critical values and  $p$ -values can be exactly computed.

When the model is overidentified and has been fit with a homoskedastic VCE, the CLR test of [Moreira \(2003\)](#), or its associated confidence interval, is reported by default. The CLR test has better power properties than the Anderson–Rubin test in the overidentified case. When the model is fit with a nonhomoskedastic VCE, a generalization of the CLR test proposed by [Finlay and Magnusson \(2009\)](#) is used. This test is equivalent to the GMM quasi-LR statistic of [Kleibergen \(2007\)](#) in the linear instrumental-variables case considered here.

Regardless of the VCE specified, the CLR test statistic has a nonstandard distribution. However, when the model has been fit with a homoskedastic VCE and there is only a single endogenous regressor, the  $p$ -value for the CLR statistic can be computed exactly using the method of [Andrews, Moreira, and Stock \(2007\)](#). Otherwise, the  $p$ -value for the CLR test statistic is obtained by simulation.

Both the Anderson–Rubin and the CLR tests (and their CIs) can be requested for any model, even though only one test (or CI) is computed and reported by default. In the just-identified case, the CLR test is equivalent to the Anderson–Rubin test.

## ▷ Example 6

We revisit the model of average rental rate as a function of average housing values and the proportion of the population living in urban areas, this time supposing we do not have access to `faminc`, the variable for median family income. We may suspect that our region indicator variables are weak instruments for `hsgnval` and therefore perform inference robust to weak instruments using `estat weakrobust`.

```
. ivregress 2sls rent pcturban (hsgnval = i.region), vce(robust)
(output omitted)
. estat weakrobust, rseed(12345)
Test robust to weak instruments
Model VCE: Robust
(1) hsgnval = 0
Cond. likelihood-ratio (CLR) test = 5.48
 Prob > CLR = 0.0255
Notes: CLR test reported by default because
 model is overidentified.
 p-value computed by simulation
 (25,000 replications).
```

Here `estat weakrobust` reports a CLR test because there are more instruments than there are endogenous regressors. We find evidence to reject the null hypothesis that the coefficient on `hsgnval` is zero, but the  $p$ -value is substantially larger than the  $p$ -value of 0.003 that is reported by `ivregress`. Note that because the model is fit with a nonhomoskedastic VCE and a CLR test is being reported, the  $p$ -value is computed by simulation. We have included a random-number seed using the `rseed()` option for reproducibility, but this is optional.

We can request a confidence interval that is robust to weak instruments for `hsgnval` with the `ci` option:

```
. estat weakrobust, ci rseed(12345)
Searching for CI bounds:
Iteration 0: Grid points = 500
Iteration 1: Grid points = 1,000
(CI computed using 1,000 grid points on [-.003591, .006664])
Confidence interval robust to weak instruments
Model VCE: Robust
```

|         | Coefficient | CLR                  |         |
|---------|-------------|----------------------|---------|
|         |             | [95% conf. interval] |         |
| hsgnval | .0015365    | .0002263             | .002857 |

```
Notes: CLR CI reported by default because model is
 overidentified.
 Computed using simulation (25,000
 replications).
```

The confidence interval comes close to containing zero. Indeed, if we specified a confidence level of 99% using `level(99)`, zero would be included. Accounting for the possibility of weak instruments, we may conclude that we cannot rule out a zero coefficient on `hsgnval`.

◀

The `ci` option, which computes Anderson–Rubin and CLR confidence intervals, is available only in the single-endogenous regressor case. When the model has been fit with a homoskedastic VCE or is just identified, confidence intervals can be computed directly by inverting the relevant test. When the

model has been fit with a nonhomoskedastic VCE and is overidentified, there is no closed form for the endpoints of the conditional likelihood confidence interval, so a gridding procedure is used to estimate the confidence intervals.

The coefficient on the endogenous regressor, as fit by `ivregress`, is reported next to the confidence interval in the output of `estat weakrobust`, `ci` for reference. However, there is generally no guarantee that the estimated coefficient will be contained in the reported confidence interval. An exception is that when the model has been fit with homoskedastic errors, the CLR confidence set will contain the LIML estimator. In the just-identified case, the Anderson–Rubin confidence set will also contain the LIML estimator. See [Moreira \(2003\)](#) for a discussion.

## □ Technical note

Unlike conventional confidence intervals, the confidence “intervals” produced by inverting Anderson–Rubin and CLR tests are not always finite intervals and may not be intervals at all. Confidence intervals can take one of five forms:

1. Finite interval  $[a, b]$ . When instruments are strong and the model is well identified, both Anderson–Rubin and CLR confidence intervals typically take this form.
2. Union of finite intervals  $[a_1, b_1] \cup [a_2, b_2] \cup \dots \cup [a_m, b_m]$ . Confidence intervals can take this form when the model VCE is nonhomoskedastic.
3. Union of (possibly infinite) intervals  $(-\infty, b_1] \cup \dots \cup [a_m, +\infty)$ . Confidence sets may take this form when instruments are weak. When the model VCE is homoskedastic, this form may only be the union of two infinite intervals.
4. Real line  $(-\infty, +\infty)$ . Confidence sets may take this form when instruments are weak.
5. Empty set  $\emptyset$ . An empty confidence interval means the test rejects every possible null value for the endogenous regressor, thus rejecting the model. The only case in which the model can be rejected in this way is when the model is overidentified and an Anderson–Rubin confidence interval is used. In other cases, an empty confidence interval means the grid used to estimate the confidence interval was too narrow, and the bounds should be widened using the `bound()` option.

For detailed discussion of unconventional confidence intervals in inference that is robust to weak instruments, see [Mikusheva and Poi \(2006\)](#), [Mikusheva \(2010\)](#), and [Kleibergen \(2007\)](#).

After GMM estimation, `estat endogenous` stores the following in `r()`:

Scalars

|        |                                                 |
|--------|-------------------------------------------------|
| r(C)   | <i>C</i> $\chi^2$ statistic                     |
| r(p_C) | <i>p</i> -value for <i>C</i> $\chi^2$ statistic |
| r(df)  | degrees of freedom                              |

`estat firststage` stores the following in `r()`:

Scalars

|           |                              |
|-----------|------------------------------|
| r(mineig) | minimum eigenvalue statistic |
|-----------|------------------------------|

Matrices

|                  |                                                  |
|------------------|--------------------------------------------------|
| r(mineigcv)      | critical values for minimum eigenvalue statistic |
| r(multiresults)  | Shea's partial $R^2$ statistics                  |
| r(singleresults) | first-stage $R^2$ and <i>F</i> statistics        |

After 2SLS estimation, `estat overid` stores the following in `r()`:

Scalars

|              |                                                |
|--------------|------------------------------------------------|
| r(lags)      | lags used in prewhitening                      |
| r(df)        | $\chi^2$ degrees of freedom                    |
| r(score)     | score $\chi^2$ statistic                       |
| r(p_score)   | <i>p</i> -value for score $\chi^2$ statistic   |
| r(basmann)   | Basmann $\chi^2$ statistic                     |
| r(p_basmann) | <i>p</i> -value for Basmann $\chi^2$ statistic |
| r(sargan)    | Sargan $\chi^2$ statistic                      |
| r(p_sargan)  | <i>p</i> -value for Sargan $\chi^2$ statistic  |

After LIML estimation, `estat overid` stores the following in `r()`:

Scalars

|                 |                                                              |
|-----------------|--------------------------------------------------------------|
| r(ar)           | Anderson–Rubin (1950) $\chi^2$ statistic                     |
| r(p_ar)         | <i>p</i> -value for Anderson–Rubin (1950) $\chi^2$ statistic |
| r(ar_df)        | $\chi^2$ degrees of freedom                                  |
| r(basmann)      | Basmann <i>F</i> statistic                                   |
| r(p_basmann)    | <i>p</i> -value for Basmann <i>F</i> statistic               |
| r(basmann_df_n) | <i>F</i> numerator degrees of freedom                        |
| r(basmann_df_d) | <i>F</i> denominator degrees of freedom                      |

After GMM estimation, `estat overid` stores the following in `r()`:

Scalars

|              |                                                          |
|--------------|----------------------------------------------------------|
| r(HansenJ)   | Hansen's <i>J</i> $\chi^2$ statistic                     |
| r(p_HansenJ) | <i>p</i> -value for Hansen's <i>J</i> $\chi^2$ statistic |
| r(J_df)      | $\chi^2$ degrees of freedom                              |

After estimation of a just-identified model, or when `ar` is specified, `estat weakrobust` stores the following in `r()`:

Scalars

|              |                                                              |
|--------------|--------------------------------------------------------------|

## Methods and formulas

Methods and formulas are presented under the following headings:

*Notation*  
*estat endogenous*  
*estat firststage*  
*estat overid*  
*estat weakrobust*  
*Homoskedastic errors*  
*Nonhomoskedastic errors*  
*Confidence intervals*

## Notation

Recall from [\[R\] ivregress](#) that the model is

$$\mathbf{y} = \mathbf{Y}\boldsymbol{\beta}_1 + \mathbf{X}_1\boldsymbol{\beta}_2 + \mathbf{u} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}$$

$$\mathbf{Y} = \mathbf{X}_1\Pi_1 + \mathbf{X}_2\Pi_2 + \mathbf{V} = \mathbf{Z}\Pi + \mathbf{V}$$

where  $\mathbf{y}$  is an  $N \times 1$  vector of the left-hand-side variable,  $N$  is the sample size,  $\mathbf{Y}$  is an  $N \times p$  matrix of  $p$  endogenous regressors,  $\mathbf{X}_1$  is an  $N \times k_1$  matrix of  $k_1$  included exogenous regressors,  $\mathbf{X}_2$  is an  $N \times k_2$  matrix of  $k_2$  excluded exogenous variables,  $\mathbf{X} = [\mathbf{Y} \ \mathbf{X}_1]$ ,  $\mathbf{Z} = [\mathbf{X}_1 \ \mathbf{X}_2]$ ,  $\mathbf{u}$  is an  $N \times 1$  vector of errors,  $\mathbf{V}$  is an  $N \times p$  matrix of errors,  $\boldsymbol{\beta} = [\boldsymbol{\beta}_1 \ \boldsymbol{\beta}_2]$  is a  $k = (p + k_1) \times 1$  vector of parameters, and  $\boldsymbol{\Pi}$  is a  $(k_1 + k_2) \times p$  vector of parameters. If a constant term is included in the model, then one column of  $\mathbf{X}_1$  contains all ones.

### estat endogenous

Partition  $\mathbf{Y}$  as  $\mathbf{Y} = [\mathbf{Y}_1 \ \mathbf{Y}_2]$ , where  $\mathbf{Y}_1$  represents the  $p_1$  endogenous regressors whose endogeneity is being tested and  $\mathbf{Y}_2$  represents the  $p_2$  endogenous regressors whose endogeneity is not being tested. If the endogeneity of all endogenous regressors is being tested,  $\mathbf{Y} = \mathbf{Y}_1$  and  $p_2 = 0$ . After GMM estimation, `estat endogenous` refits the model treating  $\mathbf{Y}_1$  as exogenous using the same type of weight matrix as requested at estimation time with the `wmatrix()` option; denote the Sargan statistic from this model by  $J_e$  and the estimated weight matrix by  $\mathbf{W}_e$ . Let  $\mathbf{S}_e = \mathbf{W}_e^{-1}$ . `estat endogenous` removes from  $\mathbf{S}_e$  the rows and columns corresponding to the variables represented by  $\mathbf{Y}_1$ ; denote the inverse of the resulting matrix by  $\mathbf{W}'_e$ . Next, `estat endogenous` fits the model treating both  $\mathbf{Y}_1$  and  $\mathbf{Y}_2$  as endogenous, using the weight matrix  $\mathbf{W}'_e$ ; denote the Sargan statistic from this model by  $J_c$ . Then,  $C = (J_e - J_c) \sim \chi^2(p_1)$ . If one simply used the  $J$  statistic from the original model fit by `ivregress` in place of  $J_c$ , then in finite samples  $J_e - J$  might be negative. The procedure used by `estat endogenous` is guaranteed to yield  $C \geq 0$ ; see [Hayashi \(2000, 220\)](#).

Let  $\hat{\mathbf{u}}_c$  denote the residuals from the model treating both  $\mathbf{Y}_1$  and  $\mathbf{Y}_2$  as endogenous, and let  $\hat{\mathbf{u}}_e$  denote the residuals from the model treating only  $\mathbf{Y}_2$  as endogenous. Then, Durbin's (1954) statistic is

$$D = \frac{\hat{\mathbf{u}}'_e \mathbf{P}_{Z\mathbf{Y}_1} \hat{\mathbf{u}}_e - \hat{\mathbf{u}}'_c \mathbf{P}_Z \hat{\mathbf{u}}_c}{\hat{\mathbf{u}}'_e \hat{\mathbf{u}}_e / N}$$

where  $\mathbf{P}_Z = \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$  and  $\mathbf{P}_{Z\mathbf{Y}_1} = [\mathbf{Z} \ \mathbf{Y}_1][(\mathbf{Z} \ \mathbf{Y}_1)'(\mathbf{Z} \ \mathbf{Y}_1)]^{-1}[\mathbf{Z} \ \mathbf{Y}_1]'$ .  $D \sim \chi^2(p_1)$ . The Wu–Hausman ([Wu 1974](#); [Hausman 1978](#)) statistic is

$$WH = \frac{(\hat{\mathbf{u}}'_e \mathbf{P}_{Z\mathbf{Y}_1} \hat{\mathbf{u}}_e - \hat{\mathbf{u}}'_c \mathbf{P}_Z \hat{\mathbf{u}}_c) / p_1}{\{\hat{\mathbf{u}}'_e \hat{\mathbf{u}}_e - (\hat{\mathbf{u}}'_c \mathbf{P}_{Z\mathbf{Y}_1} \hat{\mathbf{u}}_e - \hat{\mathbf{u}}'_c \mathbf{P}_Z \hat{\mathbf{u}}_c)\} / (N - k_1 - p - p_1)}$$

$WH \sim F(p_1, N - k_1 - p - p_1)$ . [Baum, Schaffer, and Stillman \(2003, 2007\)](#) discuss these tests in more detail.

Next, we describe Wooldridge's (1995) score test. The nonrobust version of Wooldridge's test is identical to Durbin's test. Suppose a robust covariance matrix was used at estimation time. Let  $\hat{\mathbf{e}}$  denote the sample residuals obtained by fitting the model via OLS, treating  $\mathbf{Y}$  as exogenous. We then regress each variable represented in  $\mathbf{Y}$  on  $\mathbf{Z}$ ; call the residuals for the  $j$ th regression  $\hat{\mathbf{r}}_j$ ,  $j = 1, \dots, p$ . Define  $\hat{k}_{ij} = \hat{e}_i \hat{r}_{ij}$ ,  $i = 1, \dots, N$ . We then run the regression

$$\mathbf{1} = \theta_1 \hat{\mathbf{k}}_1 + \dots + \theta_p \hat{\mathbf{k}}_p + \boldsymbol{\epsilon}$$

where  $\mathbf{1}$  is an  $N \times 1$  vector of ones and  $\boldsymbol{\epsilon}$  is a regression error term.  $N - \text{RSS} \sim \chi^2(p)$ , where RSS is the residual sum of squares from the regression just described. If instead a HAC VCE was used at estimation time, then before running the final regression we prewhiten the  $\hat{\mathbf{k}}_j$  series by using a `VAR(q)` model, where  $q$  is the number of lags specified with the `lags()` option.

The regression-based test proceeds as follows. Following Hausman (1978, 1259), we regress  $\mathbf{Y}$  on  $\mathbf{Z}$  and obtain the residuals  $\widehat{\mathbf{V}}$ . Next, we fit the augmented regression

$$\mathbf{y} = \mathbf{Y}\beta_1 + \mathbf{X}_1\beta_2 + \widehat{\mathbf{V}}\gamma + \epsilon$$

by OLS regression, where  $\epsilon$  is a regression error term. A test of the exogeneity of  $\mathbf{Y}$  is equivalent to a test of  $\gamma = \mathbf{0}$ . As Cameron and Trivedi (2005, 276) suggest, this test can be made robust to heteroskedasticity, autocorrelation, or clustering by using the appropriate robust VCE when testing  $\gamma = \mathbf{0}$ . When a nonrobust VCE is used, this test is equivalent to the Wu–Hausman test described earlier. One cannot simply fit this augmented regression via 2SLS to test the endogeneity of a subset of the endogenous regressors; Davidson and MacKinnon (1993, 229–231) discuss a test of  $\gamma = \mathbf{0}$  for the homoskedastic version of the augmented regression fit by 2SLS, but an appropriate robust test is not apparent.

### estat firststage

When the structural equation includes one endogenous regressor, `estat firststage` fits the regression

$$\mathbf{Y} = \mathbf{X}_1\pi_1 + \mathbf{X}_2\pi_2 + \mathbf{v}$$

via OLS. The  $R^2$  and adjusted  $R^2$  from that regression are reported in the output, as well as the  $F$  statistic from the Wald test of  $H_0: \pi_2 = \mathbf{0}$ . To obtain the partial  $R^2$  statistic, `estat firststage` fits the regression

$$\mathbf{M}_{\mathbf{X}_1}\mathbf{y} = \mathbf{M}_{\mathbf{X}_1}\mathbf{X}_2\xi + \epsilon$$

by OLS, where  $\epsilon$  is a regression error term,  $\xi$  is a  $k_2 \times 1$  parameter vector, and  $\mathbf{M}_{\mathbf{X}_1} = \mathbf{I} - \mathbf{X}_1(\mathbf{X}'_1\mathbf{X}_1)^{-1}\mathbf{X}'_1$ ; that is, the partial  $R^2$  is the  $R^2$  between  $\mathbf{y}$  and  $\mathbf{X}_2$  after eliminating the effects of  $\mathbf{X}_1$ . If the model contains multiple endogenous regressors and the `all` option is specified, these statistics are calculated for each endogenous regressor in turn.

To calculate Shea’s partial  $R^2$ , let  $\mathbf{y}_1$  denote the endogenous regressor whose statistic is being calculated and  $\mathbf{Y}_0$  denote the other endogenous regressors. Define  $\tilde{\mathbf{y}}_1$  as the residuals obtained from regressing  $\mathbf{y}_1$  on  $\mathbf{Y}_0$  and  $\mathbf{X}_1$ . Let  $\hat{\mathbf{y}}_1$  denote the fitted values obtained from regressing  $\mathbf{y}_1$  on  $\mathbf{X}_1$  and  $\mathbf{X}_2$ ; that is,  $\hat{\mathbf{y}}_1$  are the fitted values from the first-stage regression for  $\mathbf{y}_1$ , and define the columns of  $\widehat{\mathbf{Y}}_0$  analogously. Finally, let  $\tilde{\tilde{\mathbf{y}}}_1$  denote the residuals from regressing  $\hat{\mathbf{y}}_1$  on  $\widehat{\mathbf{Y}}_0$  and  $\mathbf{X}_1$ . Shea’s partial  $R^2$  is the simple  $R^2$  from the regression of  $\tilde{\tilde{\mathbf{y}}}_1$  on  $\tilde{\tilde{\mathbf{y}}}_1$ ; denote this as  $R^2_S$ . Shea’s adjusted partial  $R^2$  is equal to  $1 - (1 - R^2_S)(N - 1)/(N - k_Z + 1)$  if a constant term is included and  $1 - (1 - R^2_S)(N - 1)/(N - k_Z)$  if there is no constant term included in the model, where  $k_Z = k_1 + k_2$ . For one endogenous regressor, one instrument, no exogenous regressors, and a constant term,  $R^2_S$  equals the adjusted  $R^2_S$ .

The Stock and Yogo minimum eigenvalue statistic, first proposed by Cragg and Donald (1993) as a test for underidentification, is the minimum eigenvalue of the matrix

$$\mathbf{G} = \frac{1}{k_Z} \widehat{\Sigma}_{\mathbf{V}\mathbf{V}}^{-1/2} \mathbf{Y}' \mathbf{M}'_{\mathbf{X}_1} \mathbf{X}_2 (\mathbf{X}'_2 \mathbf{M}_{\mathbf{X}_1} \mathbf{X}_2)^{-1} \mathbf{X}'_2 \mathbf{M}_{\mathbf{X}_1} \mathbf{Y} \widehat{\Sigma}_{\mathbf{V}\mathbf{V}}^{-1/2}$$

where

$$\widehat{\Sigma}_{\mathbf{V}\mathbf{V}} = \frac{1}{N - k_Z} \mathbf{Y}' \mathbf{M}_Z \mathbf{Y}$$

$\mathbf{M}_Z = \mathbf{I} - \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$ , and  $\mathbf{Z} = [\mathbf{X}_1 \ \mathbf{X}_2]$ . Critical values are obtained from the tables in Stock and Yogo (2005).

## estat overid

The Sargan (1958) and Basmann (1960)  $\chi^2$  statistics are calculated by running the auxiliary regression

$$\hat{\mathbf{u}} = \mathbf{Z}\boldsymbol{\delta} + \mathbf{e}$$

where  $\hat{\mathbf{u}}$  are the sample residuals from the model and  $\mathbf{e}$  is an error term. Then, Sargan's statistic is

$$S = N \left( 1 - \frac{\hat{\mathbf{e}}'\hat{\mathbf{e}}}{\hat{\mathbf{u}}'\hat{\mathbf{u}}} \right)$$

where  $\hat{\mathbf{e}}$  are the residuals from that auxiliary regression. Basmann's statistic is calculated as

$$B = S \frac{N - k_Z}{N - S}$$

Both  $S$  and  $B$  are distributed  $\chi^2(m)$ , where  $m$ , the number of overidentifying restrictions, is equal to  $k_Z - k$ , where  $k$  is the number of endogenous regressors.

Wooldridge's (1995) score test of overidentifying restrictions is identical to Sargan's (1958) statistic under the assumption of i.i.d. and therefore is not recomputed unless a robust VCE was used at estimation time. If a heteroskedasticity-robust VCE was used, Wooldridge's test proceeds as follows. Let  $\hat{\mathbf{Y}}$  denote the  $N \times k$  matrix of fitted values obtained by regressing the endogenous regressors on  $\mathbf{X}_1$  and  $\mathbf{X}_2$ . Let  $\mathbf{Q}$  denote an  $N \times m$  matrix of excluded exogenous variables; the test statistic to be calculated is invariant to whichever  $m$  of the  $k_2$  excluded exogenous variables is chosen. Define the  $i$ th element of  $\hat{\mathbf{k}}_j$ ,  $i = 1, \dots, N$ ,  $j = 1, \dots, m$ , as

$$k_{ij} = \hat{q}_{ij} \hat{u}_i$$

where  $\hat{q}_{ij}$  is the  $i$ th element of  $\hat{\mathbf{q}}_j$ , the residuals from regressing the  $j$ th column of  $\mathbf{Q}$  on  $\hat{\mathbf{Y}}$  and  $\mathbf{X}_1$ . Finally, fit the regression

$$\mathbf{1} = \theta_1 \hat{\mathbf{k}}_1 + \dots + \theta_m \hat{\mathbf{k}}_m + \boldsymbol{\epsilon}$$

where  $\mathbf{1}$  is an  $N \times 1$  vector of ones and  $\boldsymbol{\epsilon}$  is a regression error term, and calculate the residual sum of squares, RSS. Then, the test statistic is  $W = N - \text{RSS}$ .  $W \sim \chi^2(m)$ . If a HAC VCE was used at estimation, then the  $\hat{\mathbf{k}}_j$  are prewhitened using a VAR( $p$ ) model, where  $p$  is specified using the `lags()` option.

The Anderson–Rubin (AR; 1950) test of overidentifying restrictions for use after the LIML estimator is calculated as  $\text{AR} = N(\kappa - 1)$ , where  $\kappa$  is the minimal eigenvalue of a certain matrix defined in *Methods and formulas* of [R] **ivregress**.  $\text{AR} \sim \chi^2(m)$ . (Some texts define this statistic as  $N \ln(\kappa)$  because  $\ln(x) \approx (x - 1)$  for  $x$  near 1.) Basmann's  $F$  statistic for use after the LIML estimator is calculated as  $B_F = (\kappa - 1)(N - k_Z)/m$ .  $B_F \sim F(m, N - k_Z)$ .

Hansen's  $J$  statistic is simply the sample size times the value of the GMM objective function defined in (5) of [R] **ivregress**, evaluated at the estimated parameter values. Under the null hypothesis that the overidentifying restrictions are valid,  $J \sim \chi^2(m)$ .

John Denis Sargan (1924–1996) was born in Yorkshire, UK. He pioneered the theory of instrumental-variables (IV) estimation in an article published in 1958. In the article, he also developed overidentification tests, developed significance tests, and discussed possible instruments for applied work. A year later, he wrote an article extending the theory to models containing autoregressive errors. This extension was one of his many contributions to time-series econometric analysis. For example, in 1964 he published a paper in which he developed misspecification tests for dynamic equations, along with an IV estimator for models with nonlinear parameters, and a model with a long-run equilibrium. His paper laid the foundation for other econometric methods, such as cointegration analysis, and established what would be known as the London School of Economics (LSE) approach to econometric modeling. He spent twenty years at this institution, supervising the doctoral work of many econometricians who themselves made important contributions to econometrics. In addition to Sargan’s many lasting contributions to econometrics, he also left a lasting impression on his students and colleagues through his generosity.

## estat weakrobust

In *estat weakrobust* of *Remarks and examples*, we reintroduced the model fit by `ivregress`, written in matrix form as

$$\begin{aligned} \mathbf{y} &= \mathbf{Y}\boldsymbol{\beta}_1 + \mathbf{X}_1\boldsymbol{\beta}_2 + \mathbf{u} \\ \mathbf{Y} &= \mathbf{X}_1\boldsymbol{\Pi}_1 + \mathbf{X}_2\boldsymbol{\Pi}_2 + \mathbf{V} \end{aligned}$$

The first equation is referred to as the structural equation, and the second equation is referred to as the first-stage equation.

We then derived the reduced-form equation. Below, we write the model in the form of the reduced-form equation and the first-stage equations

$$\begin{aligned} \mathbf{y} &= \mathbf{X}_1\boldsymbol{\delta}_1 + \mathbf{X}_2\boldsymbol{\delta}_2 + \boldsymbol{\epsilon} \\ \mathbf{Y} &= \mathbf{X}_1\boldsymbol{\Pi}_1 + \mathbf{X}_2\boldsymbol{\Pi}_2 + \mathbf{V} \end{aligned}$$

where  $\boldsymbol{\delta}_1 \equiv \boldsymbol{\Pi}_1\boldsymbol{\beta}_1 + \boldsymbol{\beta}_2$  and  $\boldsymbol{\delta}_2 \equiv \boldsymbol{\Pi}_2\boldsymbol{\beta}_1$ . The reduced-form coefficients  $\boldsymbol{\delta}_1$  and  $\boldsymbol{\delta}_2$  are  $k_1 \times 1$  and  $k_2 \times 1$ , respectively. Without loss of generality, we can rewrite the model to omit included exogenous regressors  $\mathbf{X}_1$  by considering  $\mathbf{y}$ ,  $\mathbf{Y}$ ,  $\mathbf{X}_2$ ,  $\boldsymbol{\epsilon}$ , and  $\mathbf{V}$  to have been replaced by their partialled-out equivalents:

$$\begin{aligned} \mathbf{y} &= \mathbf{X}_2\boldsymbol{\delta}_2 + \boldsymbol{\epsilon} \\ \mathbf{Y} &= \mathbf{X}_2\boldsymbol{\Pi}_2 + \mathbf{V} \end{aligned}$$

Our null hypothesis  $\boldsymbol{\beta}_1 = \mathbf{r}_1$  implies that  $\boldsymbol{\delta}_2 - \boldsymbol{\Pi}_2\mathbf{r}_1 = 0$ .

## Homoskedastic errors

Let  $\widehat{\boldsymbol{\Omega}} = 1/N \begin{bmatrix} \tilde{\boldsymbol{\epsilon}}'\tilde{\boldsymbol{\epsilon}} & \tilde{\boldsymbol{\epsilon}}'\widehat{\mathbf{V}} \\ \widehat{\mathbf{V}}'\tilde{\boldsymbol{\epsilon}} & \widehat{\mathbf{V}}'\widehat{\mathbf{V}} \end{bmatrix}$  be the estimated  $(p+1) \times (p+1)$  covariance matrix of  $(\boldsymbol{\epsilon}', \mathbf{V}')'$ . When the model is assumed to have homoskedastic errors, we can proceed by computing the statistics

$$\bar{S} = (\mathbf{X}_2'\mathbf{X}_2)^{-1/2}\mathbf{X}_2'(\mathbf{y} - \mathbf{Y}\mathbf{r}_1)(\mathbf{b}_0'\widehat{\boldsymbol{\Omega}}\mathbf{b}_0)^{-1/2}$$

and

$$\bar{T} = (\mathbf{X}'_2 \mathbf{X}_2)^{-1/2} \mathbf{X}'_2 [\mathbf{y}, \mathbf{Y}']' \widehat{\boldsymbol{\Omega}}^{-1} \mathbf{A}_0 (\mathbf{A}'_0 \widehat{\boldsymbol{\Omega}}^{-1} \mathbf{A}_0)^{-1/2}$$

where  $\mathbf{b}_0 = [1, -\mathbf{r}_1]$  and  $\mathbf{A}_0 = [\mathbf{r}_1, \mathbf{I}_p]'$ .

The Anderson–Rubin (1949) statistic is computed as  $\text{AR} = \bar{S}' \bar{S}$  and follows a  $\chi^2(k_2)$  distribution. When the model has been fit with the `small` option in `ivregress`, an  $F$  version of the statistic is returned, which is distributed  $F(k_2, N - k_1 - k_2)$ . This  $F$  statistic is computed using  $N/(N - k_1 - k_2) \widehat{\boldsymbol{\Omega}}$  in place of  $\widehat{\boldsymbol{\Omega}}$ .

The CLR statistic is computed as  $\text{CLR} = \bar{S}' \bar{S} - \bar{\lambda}^{\min}$ , where  $\bar{\lambda}^{\min}$  is the minimum eigenvalue of the matrix  $(\bar{S}, \bar{T})' (\bar{S}, \bar{T})$ . When the model is fit with the `small` option in `ivregress`, the statistic is computed using  $N/(N - k_1 - k_2) \widehat{\boldsymbol{\Omega}}$ . When the model is just identified,  $\text{CLR} \sim \chi^2(k_2)$ . When the model is overidentified, CLR has a nonstandard distribution. The numerical method of Andrews, Moreira, and Stock (2007) is used to obtain  $p$ -values in the single-endogenous regressor case. In the multiple-endogenous regressor case,  $p$ -values are obtained by simulation conditional on  $\bar{T}$ , as outlined in Moreira (2003).

## Nonhomoskedastic errors

When the model is fit with a nonhomoskedastic VCE, let

$$\widehat{\boldsymbol{\Sigma}} = \begin{bmatrix} \widehat{\boldsymbol{\Sigma}}_{\delta} & \widehat{\boldsymbol{\Sigma}}_{\delta \Pi} \\ \widehat{\boldsymbol{\Sigma}}_{\Pi \delta} & \widehat{\boldsymbol{\Sigma}}_{\Pi} \end{bmatrix}$$

be the  $k_2(p + 1) \times k_2(p + 1)$  estimated covariance matrix of  $\{\delta'_2, \text{Vec}(\boldsymbol{\Pi}_2)'\}'$ , where  $\text{Vec}(\cdot)$  is the column-major vectorization operator.

We compute the Anderson–Rubin statistic as

$$\text{AR}(\mathbf{r}_1) = (\mathbf{y} - \mathbf{Y}\mathbf{r}_1)' \mathbf{X}_2 (\mathbf{X}'_2 \mathbf{X}_2)^{-1} \widehat{\boldsymbol{\Psi}}(\mathbf{r}_1)^{-1} (\mathbf{X}'_2 \mathbf{X}_2)^{-1} \mathbf{X}'_2 (\mathbf{y} - \mathbf{Y}\mathbf{r}_1)$$

where  $\widehat{\boldsymbol{\Psi}}(\mathbf{r}_1) = (\mathbf{b}_0 \otimes \mathbf{I}_k)' \widehat{\boldsymbol{\Sigma}} (\mathbf{b}_0 \otimes \mathbf{I}_k)$ .

As in the homoskedastic case, AR takes on a  $\chi^2(k_2)$  distribution under the null. When the model is fit with the `small` option, the statistic is computed using a small-sample adjustment, and an  $F$  version of the statistic is returned.

To compute the CLR test statistic, let  $J(\mathbf{r}_1)$  be defined as in Finlay and Magnusson (2009) (or, equivalently, as in Kleibergen [2007]), and let  $\text{rk}(\mathbf{r}_1)$  be the rank statistic of Kleibergen and Paap (2006) (the forms of these statistics are omitted here for brevity). The test statistic is given by

$$\text{CLR}(\mathbf{r}_1) = \frac{1}{2} \left[ \text{AR}(\mathbf{r}_1) - \text{rk}(\mathbf{r}_1) + \sqrt{\{\text{AR}(\mathbf{r}_1) + \text{rk}(\mathbf{r}_1)\}^2 - 4J(\mathbf{r}_1)\text{rk}(\mathbf{r}_1)} \right]$$

In the just-identified case, CLR is equal to AR and has a  $\chi^2(k_2)$  distribution. Otherwise, CLR has a nonstandard distribution, and  $p$ -values are obtained by simulation, as outlined in Kleibergen (2007). When the model is fit with the `small` option, the statistic is computed using a small-sample adjustment.

## Confidence intervals

Confidence intervals are obtained by inverting the relevant tests. When the model is fit with a homoskedastic VCE, or when it is just identified, the Anderson–Rubin test can be inverted analytically, so the bounds of the resulting interval (or union of intervals) are computed as a closed form (see Mikushcheva [2010] for details). When the model VCE is nonhomoskedastic and the model is overidentified, the Anderson–Rubin confidence interval is obtained by a gridding procedure.

The CLR test is equivalent to the Anderson–Rubin test in the just-identified case, so its confidence intervals can be computed in the same way. In the overidentified case when errors are homoskedastic, the CLR test is inverted numerically using the method of Mikusheva (2010). When errors are nonhomoskedastic, a gridding procedure is used to obtain a confidence interval.

## Acknowledgments

We thank Keith Finlay of the US Census Bureau, Leandro Magnusson of the University of Western Australia, and Mark Schaffer of Heriot-Watt University for their Stata commands `rivtest`, discussed in Finlay and Magnusson (2009), and `weakiv`.

We thank Anna Mikusheva of MIT and Brian Poi of Poi Consulting LLC for their Stata command `condivreg`, discussed in Mikusheva and Poi (2006).

## Description

`ivtobit` fits tobit models where one or more of the covariates are endogenously determined. By default, `ivtobit` uses maximum likelihood estimation, but Newey's (1987) minimum  $\chi^2$  (two-step) estimator can be requested. Both estimators assume that the endogenous covariates are continuous and so are not appropriate for use with discrete endogenous covariates.

## Quick start

Tobit regression of  $y_1$  on  $x$  and endogenous regressor  $y_2$  that is instrumented by  $z$  where  $y_1$  is left-censored at its observed minimum

```
ivtobit y1 x (y2 = z), ll
```

Same as above, but specify that  $y_1$  is left-censored at 0 and right-censored at 20

```
ivtobit y1 x (y2 = z), ll(0) ul(20)
```

Use Newey's two-step estimator

```
ivtobit y1 x (y2 = z), ll(0) ul(20) twostep
```

Same as above, and show first-stage regression results

```
ivtobit y1 x (y2 = z), ll(0) ul(20) twostep first
```

## Menu

Statistics > Endogenous covariates > Tobit model with endogenous covariates

## Syntax

### Maximum likelihood estimator

```
ivtobit depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight] ,
 ll[(#)] ul[(#)] [mle_options]
```

### Two-step estimator

```
ivtobit depvar [varlist1] (varlist2 = varlistiv) [if] [in] [weight] , twostep
 ll[(#)] ul[(#)] [tse_options]
```

*varlist*<sub>1</sub> is the list of exogenous variables.

*varlist*<sub>2</sub> is the list of endogenous variables.

*varlist*<sub>iv</sub> is the list of exogenous variables used with *varlist*<sub>1</sub> as instruments for *varlist*<sub>2</sub>.

\*`twostep` is required. You must specify at least one of `ll`[(#)] and `ul`[(#)].

*varlist*<sub>1</sub> and *varlist*<sub>iv</sub> may contain factor variables; see [U] 11.4.3 Factor variables.

*devar*, *varlist*<sub>1</sub>, *varlist*<sub>2</sub>, and *varlist*<sub>iv</sub> may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayesboot`, `bootstrap`, `by`, `collect`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. `fp` is allowed with the maximum likelihood estimator.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`vce()`, `first`, `twostep`, and `weights` are not allowed with the `svy` prefix; see [SVY] `svy`.

`fweights`, `iwweights`, and `pweights` are allowed with the maximum likelihood estimator. `fweights` are allowed with Newey's two-step estimator. See [U] 11.1.6 `weight`.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options for ML estimator

### Model

`ll`[(#)] and `ul`[(#)] indicate the lower and upper limits for censoring, respectively. You may specify one or both. Observations with `devar` ≤ `ll`() are left-censored; observations with `devar` ≥ `ul`() are right-censored; and remaining observations are not censored. You do not have to specify the censoring values at all. It is enough to type `ll`, `ul`, or both. When you do not specify a censoring value, `ivtobit` assumes that the lower limit is the minimum observed in the data (if `ll` is specified) and that the upper limit is the maximum (if `ul` is specified).

`mle` requests that the conditional maximum-likelihood estimator be used. This is the default.

`constraints`(*constraints*); see [R] Estimation options.

### SE/Robust

`vce`(*vcetype*) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster` *clustvar*), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] `vce_option`.

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, `first` shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the tobit equation. The default is not to show these parameter estimates.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

## Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#).

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following option is available with `ivtobit` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Options for two-step estimator

## Model

`twostep` is required and requests that Newey's (1987) efficient two-step estimator be used to obtain the coefficient estimates.

`ll[ (#) ]` and `ul[ (#) ]` indicate the lower and upper limits for censoring, respectively. You may specify one or both. Observations with `depvar ≤ ll()` are left-censored; observations with `depvar ≥ ul()` are right-censored; and remaining observations are not censored. You do not have to specify the censoring values at all. It is enough to type `ll`, `ul`, or both. When you do not specify a censoring value, `ivtobit` assumes that the lower limit is the minimum observed in the data (if `ll` is specified) and that the upper limit is the maximum (if `ul` is specified).

## SE

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`twostep`) and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

## Reporting

`level(#)`; see [R] [Estimation options](#).

`first` requests that the parameters for the reduced-form equations showing the relationships between the endogenous variables and instruments be displayed. For the two-step estimator, `first` shows the first-stage regressions. For the maximum likelihood estimator, these parameters are estimated jointly with the parameters of the tobit equation. The default is not to show these parameter estimates.

*display\_options*: `noc1`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

The following option is available with `ivtobit` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

`ivtobit` fits models with censored dependent variables and endogenous covariates. You can use it to fit a tobit model when you suspect that one or more of the covariates is correlated with the error term. `ivtobit` is to tobit what `ivregress` is to linear regression analysis; see [R] [ivregress](#) for more information.

Formally, the model is

$$\begin{aligned} y_{1i}^* &= \mathbf{y}_{2i} \boldsymbol{\beta} + \mathbf{x}_{1i} \boldsymbol{\gamma} + u_i \\ \mathbf{y}_{2i} &= \mathbf{x}_{1i} \boldsymbol{\Pi}_1 + \mathbf{x}_{2i} \boldsymbol{\Pi}_2 + \mathbf{v}_i \end{aligned}$$

where  $i = 1, \dots, N$ ;  $\mathbf{y}_{2i}$  is a  $1 \times p$  vector of endogenous variables;  $\mathbf{x}_{1i}$  is a  $1 \times k_1$  vector of exogenous variables;  $\mathbf{x}_{2i}$  is a  $1 \times k_2$  vector of additional instruments; and the equation for  $\mathbf{y}_{2i}$  is written in reduced form. By assumption,  $(u_i, \mathbf{v}_i) \sim N(\mathbf{0}, \boldsymbol{\Sigma})$ .  $\boldsymbol{\beta}$  and  $\boldsymbol{\gamma}$  are vectors of structural parameters, and  $\boldsymbol{\Pi}_1$  and  $\boldsymbol{\Pi}_2$  are matrices of reduced-form parameters. We do not observe  $y_{1i}^*$ ; instead, we observe

$$y_{1i} = \begin{cases} a & y_{1i}^* < a \\ y_{1i}^* & a \leq y_{1i}^* \leq b \\ b & y_{1i}^* > b \end{cases}$$

The order condition for identification of the structural parameters is that  $k_2 \geq p$ . Presumably,  $\boldsymbol{\Sigma}$  is not block diagonal between  $u_i$  and  $\mathbf{v}_i$ ; otherwise,  $\mathbf{y}_{2i}$  would not be endogenous.

### □ Technical note

This model is derived under the assumption that  $(u_i, \mathbf{v}_i)$  is independent and identically distributed multivariate normal for all  $i$ . The `vce(cluster clustvar)` option can be used to control for a lack of independence. As with the standard tobit model without endogeneity, if  $u_i$  is heteroskedastic, point estimates will be inconsistent.

□

## ► Example 1: Estimation and parameter interpretation

We model the number of hours per week that high school boys spend using social media (`hsocial`). The data collection process caused the observations on the number of hours spent to be censored at 12 hours. A tobit-type model is therefore reasonable for our data.

We model each boy's number of hours spent using social media as a function of whether he has a smartphone (`sphone`), whether he has a computer at home (`computer`), the year in high school in which he is enrolled (`year`), and the hours per week he spends studying (`hstudy`).

We believe that there are unobservable variables that simultaneously affect `hstudy` and `hsocial`, which is to say that `hstudy` is endogenous. Because `hstudy` is endogenous, we must model it as well. Our model for the endogenous `hstudy` always includes the exogenous covariates used to model the outcome `hsocial`. We must also include at least one covariate in the model for the endogenous `hstudy` that was not included in the model for the outcome `hsocial`.

We use `ivtobit` with the default maximum-likelihood estimator to model the endogenous variable `hstudy` as a function of the highest educational degree attained by their parents (`pedu`), the time spent watching television (`tvhours`), and the exogenous covariates used to model `hsocial`.

```

The coefficients in the table tell us how much the linear prediction for the outcome changes when there is a change in a covariate.

Below the table, we see a Wald test for whether the correlation between the residuals from the main equation (predicting `hstudy`) and the residuals from the auxiliary equation (predicting `hsocial`) is 0. The correlation itself is 0.47 and shown in the table as `corr(e.hstudy, e.hsocia1)`. If the test statistic is not significant, there is not sufficient information in the sample to reject the null hypothesis of no endogeneity. In our example, we reject the null hypothesis that supports our choice of a tobit model that accounts for endogeneity.

◀

## □ Technical note

In the tobit model with endogenous covariates, we assume that  $(u_i, v_i)$  is multivariate normal with covariance matrix

$$\text{Var}(u_i, v_i) = \Sigma = \begin{bmatrix} \sigma_u^2 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}$$

Using the properties of the multivariate normal distribution,  $\text{Var}(u_i | v_i) \equiv \sigma_{u|v}^2 = \sigma_u^2 - \Sigma'_{21} \Sigma_{22}^{-1} \Sigma_{21}$ . Calculating the marginal effects on the conditional expected values of the observed and latent dependent variables and on the probability of censoring requires an estimate of  $\sigma_{u|v}^2$ . Unlike the default maximum-likelihood estimator, the two-step estimator identifies only  $\sigma_{u|v}^2$ , not  $\sigma_u^2$ , so only the linear prediction and its standard error are available after you have used the `twostep` option.

| e(asbalanced)   | factor variables <code>fvset</code> as <code>asbalanced</code> |
| e(asobserved)   | factor variables <code>fvset</code> as <code>asobserved</code> |
| Matrices        |                                                                |
| e(b)            | coefficient vector                                             |
| e(Cns)          | constraints matrix                                             |
| e(V)            | variance–covariance matrix of the estimators                   |
| e(V_modelbased) | model-based variance                                           |
| Functions       |                                                                |
| e(sample)       | marks estimation sample                                        |

In addition to the above, the following is stored in `r()`:

|                       |                                                                                                                            |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|
| Matrices              |                                                                                                                            |
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

The estimation procedure used by `ivtobit` is similar to that used by `ivprobit`. For compactness, we write the model as

$$y_{1i}^* = z_i \delta + u_i$$

$$y_{2i} = x_i \Pi + v_i$$

where  $z_i = (y_{2i}, x_{1i})$ ,  $x_i = (x_{1i}, x_{2i})$ ,  $\delta = (\beta', \gamma')'$ , and  $\Pi = (\Pi_1', \Pi_2')'$ . We do not observe  $y_{1i}^*$ ; instead, we observe

$$y_{1i} = \begin{cases} a & y_{1i}^* < a \\ y_{1i}^* & a \leq y_{1i}^* \leq b \\ b & y_{1i}^* > b \end{cases}$$

$(u_i, v_i)$  is distributed multivariate normal with mean zero and covariance matrix

$$\Sigma = \begin{bmatrix} \sigma_u^2 & \Sigma'_{21} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}$$

Using the properties of the multivariate normal distribution, we can write  $u_i = \mathbf{v}'_i \boldsymbol{\alpha} + \epsilon_i$ , where  $\boldsymbol{\alpha} = \boldsymbol{\Sigma}_{22}^{-1} \boldsymbol{\Sigma}_{21}$ ;  $\epsilon_i \sim N(0; \sigma_{u|v}^2)$ , where  $\sigma_{u|v}^2 = \sigma_u^2 - \boldsymbol{\Sigma}'_{21} \boldsymbol{\Sigma}_{22}^{-1} \boldsymbol{\Sigma}_{21}$ ; and  $\epsilon_i$  is independent of  $\mathbf{v}_i$ ,  $\mathbf{z}_i$ , and  $\mathbf{x}_i$ .

The likelihood function is straightforward to derive because we can write the joint density  $f(y_{1i}, \mathbf{y}_{2i} | \mathbf{x}_i)$  as  $f(y_{1i} | \mathbf{y}_{2i}, \mathbf{x}_i) f(\mathbf{y}_{2i} | \mathbf{x}_i)$ . We have that

$$\ln f(\mathbf{y}_{2i} | \mathbf{x}_i) = -\frac{1}{2} (p \ln 2\pi + \ln |\boldsymbol{\Sigma}_{22}| + \mathbf{v}'_i \boldsymbol{\Sigma}_{22}^{-1} \mathbf{v}_i)$$

and

$$\ln f(y_{1i} | \mathbf{y}_{2i}, \mathbf{x}_i) = \begin{cases} \ln \left\{ 1 - \Phi \left( \frac{m_i - a}{\sigma_{u|v}} \right) \right\} & y_{1i} = a \\ -\frac{1}{2} \left\{ \ln 2\pi + \ln \sigma_{u|v}^2 + \frac{(y_{1i} - m_i)^2}{\sigma_{u|v}^2} \right\} & a < y_{1i} < b \\ \ln \Phi \left( \frac{m_i - b}{\sigma_{u|v}} \right) & y_{1i} = b \end{cases}$$

where

$$m_i = \mathbf{z}_i \boldsymbol{\delta} + (\mathbf{y}_{2i} - \mathbf{x}_i \boldsymbol{\Pi}) \boldsymbol{\Sigma}_{22}^{-1} \boldsymbol{\Sigma}_{21}$$

and  $\Phi(\cdot)$  is the normal distribution function so that the log likelihood for observation  $i$  is

$$\ln L_i = w_i \{ \ln f(y_{1i} | \mathbf{y}_{2i}, \mathbf{x}_i) + \ln f(\mathbf{y}_{2i} | \mathbf{x}_i) \}$$

where  $w_i$  is the weight for observation  $i$  or one if no weights were specified. Instead of estimating  $\sigma_{u|v}$  and  $\sigma_v$  directly, we estimate  $\ln \sigma_{u|v}$  and  $\ln \sigma_v$ .

With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] [\\_robust](#), particularly [Maximum likelihood estimators](#) and [Methods and formulas](#).

The maximum likelihood version of `ivtobit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] [Variance estimation](#).

The two-step estimates are obtained using Newey's (1987) minimum  $\chi^2$  estimator. For more details on the minimum  $\chi^2$  estimator, see [R] [ivprobit](#).

## Acknowledgments

The two-step estimator is based on the `tobitiv` command written by Jonah Gelbach of the University of California at Berkeley Law School and the `ivtobit` command written by Joe Harkness of the University of Connecticut.

## Postestimation commands

The following postestimation commands are of special interest after `ivtobit`:

| Command                        | Description                                                                                        |
|--------------------------------|----------------------------------------------------------------------------------------------------|
| <code>estat correlation</code> | report the correlation matrix of the errors of the dependent variable and the endogenous variables |
| <code>estat covariance</code>  | report the covariance matrix of the errors of the dependent variable and the endogenous variables  |

These commands are not appropriate after the two-step estimator or with `svy` estimation results.

The following standard postestimation commands are also available:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| * <code>estat ic</code>      | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * † <code>forecast</code>    | dynamic forecasts and simulations                                                                                                       |
| † <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| * † <code>lrtest</code>      | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | linear predictions and their SEs, probabilities, etc.                                                                                   |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| * <code>suest</code>         | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*`estat ic`, `forecast`, `lrtest`, and `suest` are not appropriate after `ivtobit`, `twostep`.

† `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as structural functions, linear predictions, standard errors, probabilities, and expected values.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

After ML

```
predict [type] newvar [if] [in] [, statistic asfmethod]
```

```
predict [type] { stub* | newvarlist } [if] [in] , scores
```

After twostep

```
predict [type] newvar [if] [in] [, twostep_statistic]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

|                         |                                                                        |
|-------------------------|------------------------------------------------------------------------|
| Main                    |                                                                        |
| <code>xb</code>         | linear prediction excluding endogeneity; the default                   |
| <code>mean</code>       | linear prediction accounting for endogeneity                           |
| <code>stdp</code>       | standard error of the linear prediction                                |
| <code>stdf</code>       | standard error of the forecast                                         |
| <code>pr(a,b)</code>    | $\Pr(a < y_j < b)$ accounting for endogeneity                          |
| <code>e(a,b)</code>     | $E(y_j   a < y_j < b)$ accounting for endogeneity                      |
| <code>ystar(a,b)</code> | $E(y_j^*, y_j^* = \max\{a, \min(y_j, b)\})$ accounting for endogeneity |

`stdf` is not allowed with `svy` estimation results.

where  $a$  and  $b$  may be numbers or variables;  $a$  missing ( $a \geq .$ ) means  $-\infty$ , and  $b$  missing ( $b \geq .$ ) means  $+\infty$ ; see [U] 12.2.1 Missing values.

| <i>asfmethod</i> | Description |
|------------------|-------------|
|------------------|-------------|

|                       |                                          |
|-----------------------|------------------------------------------|
| Main                  |                                          |
| <code>asf</code>      | average structural function; the default |
| <code>fixedasf</code> | fixed average structural function        |

| <i>twostep_statistic</i> | Description |
|--------------------------|-------------|
|--------------------------|-------------|

|                   |                                         |
|-------------------|-----------------------------------------|
| Main              |                                         |
| <code>xb</code>   | linear prediction; the default          |
| <code>stdp</code> | standard error of the linear prediction |

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

## Options for predict

Main

`xb`, the default, calculates the linear prediction.

`mean` calculates the linear prediction. Results depend on how the endogeneity complication is handled, which is determined by the `asf` or `fixedasf` option. `mean` is not available with the two-step estimator.

`stdp` calculates the standard error of the linear prediction. It can be thought of as the standard error of the predicted expected value or mean for the observation's covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see *Methods and formulas* in [R] **regress postestimation**.

`pr(a,b)` calculates  $\Pr(a < y_j < b | \mathbf{z}_j)$ , the probability that  $y_j | \mathbf{z}_j$  would be observed in the interval  $(a, b)$ .

$a$  and  $b$  may be specified as numbers or variable names;  $lb$  and  $ub$  are variable names;

`pr(20,30)` calculates  $\Pr(20 < y_j < 30 | \mathbf{z}_j)$ ;

`pr(lb,ub)` calculates  $\Pr(lb < y_j < ub | \mathbf{z}_j)$ ; and

`pr(20,ub)` calculates  $\Pr(20 < y_j < ub | \mathbf{z}_j)$ .

$a$  missing ( $a \geq .$ ) means  $-\infty$ ; `pr(. ,30)` calculates  $\Pr(-\infty < y_j < 30 | \mathbf{z}_j)$ ;

`pr(lb,30)` calculates  $\Pr(-\infty < y_j < 30 | \mathbf{z}_j)$  in observations for which  $lb \geq .$

and calculates  $\Pr(lb < y_j < 30 | \mathbf{z}_j)$  elsewhere.

$b$  missing ( $b \geq .$ ) means  $+\infty$ ; `pr(20, .)` calculates  $\Pr(+\infty > y_j > 20 | \mathbf{z}_j)$ ;

`pr(20,ub)` calculates  $\Pr(+\infty > y_j > 20 | \mathbf{z}_j)$  in observations for which  $ub \geq .$

and calculates  $\Pr(20 < y_j < ub | \mathbf{z}_j)$  elsewhere.

Results depend on how the endogeneity complication is handled, which is determined by the `asf` or `fixedasf` option.

`pr(a,b)` is not available with the two-step estimator.

`e(a,b)` calculates  $E(y_j | a < y_j < b)$ , the expected value of  $y_j | \mathbf{z}_j$  conditional on  $y_j | \mathbf{z}_j$  being in the interval  $(a, b)$ , meaning that  $y_j | \mathbf{z}_j$  is truncated.  $a$  and  $b$  are specified as they are for `pr()`. Results depend on how the endogeneity complication is handled, which is determined by the `asf` or `fixedasf` option. `e(a,b)` is not available with the two-step estimator.

`ystar(a,b)` calculates  $E(y_j^*)$ , where  $y_j^* = a$  if  $\mathbf{z}_i \boldsymbol{\delta} + u_j \leq a$ ,  $y_j^* = b$  if  $\mathbf{z}_i \boldsymbol{\delta} + u_j \geq b$ , and  $y_j^* = \mathbf{z}_i \boldsymbol{\delta} + u_j$  otherwise, meaning that  $y_j^*$  is censored.  $a$  and  $b$  are specified as they are for `pr()`. Results depend on how the endogeneity complication is handled, which is determined by the `asf` or `fixedasf` option.

`ystar(a,b)` is not available with the two-step estimator.

`asf` and `fixedasf` determine how the average structural function (ASF) of the specified statistic is computed. These options are not allowed with `xb`, `stdp`, or `stdf`.

`asf` is the default for the ML estimator when the mean,  $\text{pr}(a, b)$ ,  $e(a, b)$ , or  $\text{ystar}(a, b)$  statistic is specified. `asf` computes the ASF of the specified statistic. It is the statistic conditional on the errors of the endogenous variable equations. Put another way, it is the statistic accounting for the correlation of the endogenous covariates with the errors of the main equation. Derivatives and contrasts based on `asf` have a structural interpretation. See `margins` for computing derivatives and contrasts.

`fixedasf` calculates a fixed ASF. It is the specified statistic using only the coefficients and variables of the outcome equation. `fixedasf` does not condition on the errors of the endogenous variable equations. Contrasts between two fixed counterfactuals averaged over the whole sample have a potential-outcome interpretation. Intuitively, it is as if the values of the covariates were fixed at a value exogenously by fiat. See `margins` for computing derivatives and contrasts.

To be clear, derivatives and contrasts between two fixed counterfactuals using the default `asf` option also have a potential-outcome interpretation. And, unlike `fixedasf`, they retain that interpretation when computed over subpopulations for both linear and nonlinear models.

`scores`, not available with `twostep`, calculates equation-level score variables.

For models with one endogenous regressor, five new variables are created.

The first new variable will contain  $\partial \ln L / \partial (z_i \delta)$ .

The second new variable will contain  $\partial \ln L / \partial (x_i \mathbf{\Pi})$ .

The third new variable will contain  $\partial \ln L / \partial \alpha$ .

The fourth new variable will contain  $\partial \ln L / \partial \ln \sigma_{u|v}$ .

The fifth new variable will contain  $\partial \ln L / \partial \ln \sigma_v$ .

For models with  $p$  endogenous regressors,  $p + \{(p + 1)(p + 2)\} / 2 + 1$  new variables are created.

The first new variable will contain  $\partial \ln L / \partial (z_i \delta)$ .

The second through  $(p + 1)$ th new score variables will contain  $\partial \ln L / \partial (x_i \mathbf{\Pi}_k)$ ,  $k = 1, \dots, p$ , where  $\mathbf{\Pi}_k$  is the  $k$ th column of  $\mathbf{\Pi}$ .

The remaining score variables will contain the partial derivatives of  $\ln L$  with respect to the  $(p + 1)(p + 2) / 2$  ancillary parameters.

# margins

## Description for margins

`margins` estimates margins of response for linear predictions, probabilities, and expected values.

## Menu for margins

| <code>stdp</code> | not allowed with margins       |

Statistics not allowed with margins are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## estat

### Description for estat

`estat correlation` displays the correlation matrix of the errors of the dependent variable and the endogenous variables.

`estat covariance` displays the covariance matrix of the errors of the dependent variable and the endogenous variables.

`estat correlation` and `estat covariance` are not allowed after the `ivprobit` two-step estimator.

### Menu for estat

Statistics > Postestimation

### Syntax for estat

*Correlation matrix*

```
estat correlation [, border(bspec) left(#) format(%fmt)]
```

*Covariance matrix*

```
estat covariance [, border(bspec) left(#) format(%fmt)]
```

### Options for estat

Main

`border`(*bspec*) sets border style of the matrix display. The default is `border(a11)`.

`left`(#) sets the left indent of the matrix display. The default is `left(2)`.

`format`(%*fmt*) specifies the format for displaying the individual elements of the matrix. The default is `format(%9.0g)`.

## Remarks and examples

Remarks are presented under the following headings:

*Marginal effects*

*Obtaining predicted values*

### Marginal effects

Below, we discuss the interpretation of predictions with the `asf` and `fixedasf` options for the ML estimator using `margins`.

The model is defined by two equations. The first is the equation for the outcome of interest, given by

$$y_{1i}^* = \mathbf{y}_{2i}\boldsymbol{\beta} + \mathbf{x}_{1i}\boldsymbol{\gamma} + u_i$$

where we do not observe  $y_{1i}^*$ ; instead, we observe

$$y_{1i} = \begin{cases} a & y_{1i}^* < a \\ y_{1i}^* & a \leq y_{1i}^* \leq b \\ b & y_{1i}^* > b \end{cases}$$

The second is the equation for the endogenous covariates,  $\mathbf{y}_{2i}$ ,

$$\mathbf{y}_{2i} = \mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2 + \mathbf{v}_i$$

This last equation is the difference between a standard tobit model and the model fit by `ivtobit`.  $\mathbf{y}_{2i}$  is modeled by an exogenous component,  $\mathbf{x}_{1i}\boldsymbol{\Pi}_1 + \mathbf{x}_{2i}\boldsymbol{\Pi}_2$ , and a component that is correlated with  $u_i$  and causes the endogeneity problem,  $\mathbf{v}_i$ . The ASF linear prediction conditions on an estimate of  $\hat{\mathbf{v}}_i$ . It is given by

$$\begin{aligned} \widehat{m}_i &= \widehat{E}(y_{1i} | \mathbf{x}_{1i}, \mathbf{x}_{2i}, y_{2i}, \hat{\mathbf{v}}_i) \\ \widehat{m}_i &= \mathbf{y}_{2i}\widehat{\boldsymbol{\theta}}_1 + \mathbf{x}_{1i}\widehat{\boldsymbol{\theta}}_2 + \hat{\mathbf{v}}_i\widehat{\boldsymbol{\theta}}_3 \end{aligned}$$

Because the correlation between  $\mathbf{v}_i$  and  $u_i$  is the problem we intended to address, conditioning on  $\mathbf{v}_i$  purges the model of endogeneity. Using the ASF, we can get derivatives and contrast. See [Wooldridge \(2010\)](#) and [Blundell and Powell \(2003\)](#) for an in-depth discussion of ASFs and their interpretation.

The fixed ASF, estimated when the `fixedasf` option is specified, has a different interpretation. Suppose we wanted to analyze  $\mathbf{y}_{2i}\beta + \mathbf{x}_{1i}\gamma + u_i$  at two different values of  $\mathbf{y}_2$ , the original  $\mathbf{y}_2$  and  $\mathbf{y}_2 + 1$ . We want the average difference at these two points for the given values of the other covariates. The values of the covariates are not arrived at via the model; they are fixed by fiat. You can think of them as potential outcomes. The difference of the two values of  $\mathbf{y}_2$  is given by

$$\{(\mathbf{y}_{2i} + 1)\beta + \mathbf{x}_{1i}\gamma + u_i\} - (\mathbf{y}_{2i}\beta + \mathbf{x}_{1i}\gamma + u_i)$$

If we average over the distribution of  $u$ , we obtain

$$E\{(\mathbf{y}_{2i} + 1)\beta + \mathbf{x}_{1i}\gamma\} - E(\mathbf{y}_{2i}\beta + \mathbf{x}_{1i}\gamma)$$

We do not account for endogeneity because the values of the covariates are given and fixed. If the research question you are pursuing after fitting the model has this interpretation, `fixedasf` gives you an adequate prediction. If, however, you do not want to treat the covariates as fixed, you should account for endogeneity and use `asf` predictions.

### ▷ Example 1: Obtaining marginal effects

We can obtain average marginal effects by using the `margins` command after `ivtobit`. For the social-media model of [example 1](#) in [\[R\] ivtobit](#), suppose that we wanted to know the average marginal effects on the probability of spending more than 12 hours using social media. Average marginal effects are equivalent to estimating how a change in a covariate affects every individual in our sample and taking the average of these effects. The effect of each covariate is estimated with all other covariates kept at their observed values.

```
. use https://www.stata-press.com/data/r19/smedia
(Fictional data on hours spent on social media)
. ivtobit hsocial i.sphone i.computer i.year (hstudy = tvhours i.pedu), ul(12)
(output omitted)
. margins, dydx(*) predict(p(12, .))
Average marginal effects Number of obs = 1,324
Model VCE: OIM
Expression: Pr(hsocial>12), predict(p(12, .))
dy/dx wrt: hstudy 1.sphone 1.computer 2.year 3.year 4.year
```

|            | Delta-method |           |        | z     | P> z      | [95% conf. interval] |  |
|------------|--------------|-----------|--------|-------|-----------|----------------------|--|
|            | dy/dx        | std. err. |        |       |           |                      |  |
| hstudy     | -.1508219    | .0044544  | -33.86 | 0.000 | -.1595523 | -.1420914            |  |
| 1.sphone   | .3943071     | .0085181  | 46.29  | 0.000 | .3776119  | .4110022             |  |
| 1.computer | .3993489     | .0082484  | 48.42  | 0.000 | .3831824  | .4155154             |  |
| year       |              |           |        |       |           |                      |  |
| 2          | .0663908     | .0120746  | 5.50   | 0.000 | .042725   | .0900567             |  |
| 3          | .1334667     | .012488   | 10.69  | 0.000 | .1089908  | .1579426             |  |
| 4          | .2343393     | .0123729  | 18.94  | 0.000 | .2100888  | .2585897             |  |

Note: dy/dx for factor levels is the discrete change from the base level.

Having a smartphone increases the probability of spending more than 12 hours on social media by 0.39, on average. Any additional study time decreases the probability of spending more than 12 hours using social media by 0.15, on average. The other average marginal effects are interpreted similarly. All effects above have a structural interpretation because we are conditioning on the level of endogeneity. See Wooldridge (2010) and Blundell and Powell (2003) for an in-depth discussion of ASFs and their interpretation.

## Obtaining predicted values

After fitting your model with `ivtobit`, you can obtain the linear prediction and its standard error for both the estimation sample and other samples by using the `predict` command. If you used the ML estimator, you can also obtain the linear prediction, the conditional expected values of the observed and latent dependent variables, and the probability of observing the dependent variable in a specified interval—each of these can be computed with an ASF or a fixed ASF interpretation. In addition, with the ML estimator, you can obtain the standard error of the forecast. See [U] 20 Estimation and postestimation commands and [R] `predict`.

## Stored results

`estat correlation` stores the following results in `r()`:

Matrices

`r(corr)` correlation matrix of the errors

`estat covariance` stores the following results in `r()`:

Matrices

`r(cov)` covariance matrix of the errors

## Methods and formulas

The linear prediction is calculated as  $z_i \hat{\delta}$ , where  $\hat{\delta}$  is the estimated value of  $\delta$ , and  $z_i$  and  $\delta$  are defined in (1a) of [R] `ivtobit`. Expected values and probabilities are calculated using the same formulas as those used by the standard tobit model. However, when we use the default `asf` option with `mean`, `pr(a, b)`, `e(a, b)`, or `ystar(a, b)`, instead of evaluating the standard normal cumulative density and probability density at the linear prediction, we evaluate expected values and probabilities at  $\hat{m}_i$ , where  $\hat{m}_i$  is defined in *Methods and formulas* of [R] `ivtobit`. Using  $\hat{m}_i$  instead of  $z_i \hat{\delta}$  in the formulas produces the ASF, which accounts for endogeneity. The fixed ASF, obtained with the `fixedasf` option, evaluates the statistic at  $z_i \hat{\delta}$ .

## Description

`jackknife` performs jackknife estimation of the specified statistics (or expressions) for a Stata command or a user-written program. Statistics are jackknifed by estimating the command once for each observation or cluster in the dataset, leaving the associated observation or cluster out of the calculations. `jackknife` is designed for use with nonestimation commands, functions of coefficients, or user-written programs. To jackknife coefficients, we recommend using the `vce(jackknife)` option when allowed by the estimation command.

## Quick start

Jackknife estimate of the standard deviation of `v1` returned by `summarize` in `r(sd)`

```
jackknife sd=r(sd), rclass: summarize v1
```

Jackknife estimate of the statistic `r(mystat)` returned by `rclass` program `myprog1` that returns the sample size in `r(N)`

```
jackknife stat=r(mystat), rclass: myprog1 v1
```

Same as above, and save the results from each replication in `mydata.dta`

```
jackknife stat=r(mystat), rclass saving(mydata): myprog1 v1
```

Jackknife estimate of a difference in coefficients estimated by `regress`

```
jackknife diff=(_b[x2]-_b[x1]): regress y x1 x2 x3
```

Jackknife estimate of the statistic `e(mystat)` returned by `eclass` program `myprog2` that returns the sample size in `e(N)`

```
jackknife stat=e(mystat), eclass: myprog2 y x1 x2 x3
```

Jackknife estimates of coefficients stored in `e(b)` by `myprog2`

```
jackknife _b, eclass: myprog2 y x1 x2 x3
```

Add variables containing the pseudovalues of the coefficients to the dataset

```
jackknife _b, eclass keep: myprog2 y x1 x2 x3
```

| <b>Advanced</b>                           |                                                                                                                                                        |
| <code>nodrop</code>                       | do not drop observations                                                                                                                               |
| <code>reject(<i>exp</i>)</code>           | identify invalid results                                                                                                                               |
| <code>coeflegend</code>                   | display legend instead of statistics                                                                                                                   |

*command* is any command that follows standard Stata syntax. All weight types supported by *command* are allowed except `aweight`s; see [\[U\] 11.1.6 weight](#).

`collect` and `svy` are allowed; see [\[U\] 11.1.10 Prefix commands](#).

`coeflegend` does not appear in the dialog box.

See [\[U\] 20 Estimation and postestimation commands](#) for more capabilities of estimation commands.

*exp\_list* contains     (*name*: *elist*)  
                           *elist*  
                           *eexp*

*elist* contains        *newvar* = (*exp*)  
                           (*exp*)

*eexp* is                *specname*  
                           [*eqno*]*specname*

*specname* is         \_b  
                           \_b []  
                           \_se  
                           \_se []

*eqno* is              ##  
                           *name*

*exp* is a standard Stata expression; see [U] 13 Functions and expressions.

Distinguish between [], which are to be typed, and [], which indicate optional arguments.

## Options

Main

*e*class, *r*class, and *n*(*exp*) specify where *command* stores the number of observations on which it based the calculated results. We strongly advise you to specify one of these options.

*e*class specifies that *command* store the number of observations in *e*(*N*).

*r*class specifies that *command* store the number of observations in *r*(*N*).

*n*(*exp*) specifies an expression that evaluates to the number of observations used. Specifying *n*(*r*(*N*)) is equivalent to specifying the *r*class option. Specifying *n*(*e*(*N*)) is equivalent to specifying the *e*class option. If *command* stores the number of observations in *r*(*N*1), specify *n*(*r*(*N*1)).

If you specify no options, *jackknife* will assume *e*class or *r*class, depending on which of *e*(*N*) and *r*(*N*) is not missing (in that order). If both *e*(*N*) and *r*(*N*) are missing, *jackknife* assumes that all observations in the dataset contribute to the calculated result. If that assumption is incorrect, the reported standard errors will be incorrect. For instance, say that you specify

```
. jackknife coef=_b[x2]: myreg y x1 x2 x3
```

where *myreg* uses *e*(*n*) instead of *e*(*N*) to identify the number of observations used in calculations. Further assume that observation 42 in the dataset has *x*3 equal to missing. The 42nd observation plays no role in obtaining the estimates, but *jackknife* has no way of knowing that and will use the wrong *N*. If, on the other hand, you specify

```
. jackknife coef=_b[x2], n(e(n)): myreg y x1 x2 x3
```

*jackknife* will notice that observation 42 plays no role. The *n*(*e*(*n*)) option is specified because *myreg* is an estimation command but it stores the number of observations used in *e*(*n*) (instead of the standard *e*(*N*)). When *jackknife* runs the regression omitting the 42nd observation, *jackknife* will observe that *e*(*n*) has the same value as when *jackknife* previously ran the regression using all the observations. Thus *jackknife* will know that *myreg* did not use the observation.

## Options

`cluster(varlist)` specifies the variables identifying sample clusters. If `cluster()` is specified, one cluster is left out of each call to *command*, instead of 1 observation.

`idcluster(newvar)` creates a new variable containing a unique integer identifier for each resampled cluster, starting at 1 and leading up to the number of clusters. This option may be specified only when the `cluster()` option is specified. `idcluster()` helps identify the cluster to which a pseudo-value belongs.

`saving(filename[ , suboptions ])` creates a Stata data file (.dta file) consisting of (for each statistic in *exp-list*) a variable containing the replicates.

`double` specifies that the results for each replication be saved as doubles, meaning 8-byte reals. By default, they are saved as floats, meaning 4-byte reals. This option may be used without the `saving()` option to compute the variance estimates by using double precision.

`every(#)` specifies that results be written to disk every #th replication. `every()` should be specified only in conjunction with `saving()` when *command* takes a long time for each replication. This option will allow recovery of partial results should some other software crash your computer. See [P] [postfile](#).

`replace` specifies that *filename* be overwritten if it exists. This option does not appear in the dialog box.

`keep` specifies that new variables be added to the dataset containing the pseudo-values of the requested statistics. For instance, if you typed

```
. jackknife coef=_b[x2], eclass keep: regress y x1 x2 x3
```

new variable `coef` would be added to the dataset containing the pseudo-values for `_b[x2]`. Let  $b$  be the value of `_b[x2]` when all observations are used to fit the model, and let  $b(j)$  be the value when the  $j$ th observation is omitted. The pseudo-values are defined as

$$\text{pseudo-value}_j = N\{b - b(j)\} + b(j)$$

where  $N$  is the number of observations used to produce  $b$ .

When the `cluster()` option is specified, each cluster is given at most one nonmissing pseudo-value. The `keep` option implies the `nodrop` option.

`mse` specifies that `jackknife` compute the variance by using deviations of the replicates from the observed value of the statistics based on the entire dataset. By default, `jackknife` computes the variance by using deviations of the pseudo-values from their mean.

## Reporting

`level(#)`; see [R] [Estimation options](#).

`notable` suppresses the display of the table of results.

`noheader` suppresses the display of the table header. This option implies `nolegend`.

`nolegend` suppresses the display of the table legend. The table legend identifies the rows of the table with the expressions they represent.

`verbose` specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed.

`nodots` and `dots(#)` specify whether to display replication dots. By default, one dot character is displayed for each successful replication. An “x” is displayed if *command* returns an error or if any value in *exp\_list* is missing. You can also control whether dots are displayed using `set dots`; see [R] [set](#).

`nodots` suppresses display of the replication dots.

`dots(#)` displays dots every # replications. `dots(0)` is a synonym for `nodots`.

`noisily` specifies that any output from *command* be displayed. This option implies the `nodots` option.

`trace` causes a trace of the execution of *command* to be displayed. This option implies the `noisily` option.

`title(text)` specifies a title to be displayed above the table of jackknife results; the default title is `Jackknife results` or what is produced in `e(title)` by an estimation command.

*display\_options*: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `no1stretch`; see [R] [Estimation options](#).

*eform\_option* causes the coefficient table to be displayed in exponentiated form; see [R] [eform\\_option](#). *command* determines which *eform\_option* is allowed (`eform(string)` and `eform` are always allowed).

*command* determines which of the following are allowed (`eform(string)` and `eform` are always allowed):

| <i>eform_option</i>        | Description                                                     |
|----------------------------|-----------------------------------------------------------------|
| <code>eform(string)</code> | use <i>string</i> for the column title                          |
| <code>eform</code>         | exponentiated coefficient, <i>string</i> is <code>exp(b)</code> |
| <code>hr</code>            | hazard ratio, <i>string</i> is <code>Haz. ratio</code>          |
| <code>shr</code>           | subhazard ratio, <i>string</i> is <code>SHR</code>              |
| <code>irr</code>           | incidence-rate ratio, <i>string</i> is <code>IRR</code>         |
| <code>or</code>            | odds ratio, <i>string</i> is <code>Odds ratio</code>            |
| <code>rrr</code>           | relative-risk ratio, <i>string</i> is <code>RRR</code>          |

#### Advanced

`nodrop` prevents observations outside `e(sample)` and the `if` and `in` qualifiers from being dropped before the data are resampled.

`reject(exp)` identifies an expression that indicates when results should be rejected. When *exp* is true, the resulting values are reset to missing values.

The following option is available with `jackknife` but is not shown in the dialog box:

`coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

*Introduction*  
*Using jackknife*  
*Jackknifed standard deviation*  
*Collecting multiple statistics*  
*Collecting coefficients*

### Introduction

Although the jackknife—developed in the late 1940s and early 1950s—is of largely historical interest today, it is still useful in searching for overly influential observations. This feature is often forgotten. In any case, the jackknife is

- an alternative, first-order unbiased estimator for a statistic;
- a data-dependent way to calculate the standard error of the statistic and to obtain significance levels and confidence intervals; and
- a way of producing measures called pseudovalues for each observation, reflecting the observation’s influence on the overall statistic.

The idea behind the simplest form of the jackknife—the one implemented here—is to repeatedly calculate the statistic in question, each time omitting just one of the dataset’s observations. Assume that our statistic of interest is the sample mean. Let  $y_j$  be the  $j$ th observation of our data on some measurement  $y$ , where  $j = 1, \dots, N$  and  $N$  is the sample size. If  $\bar{y}$  is the sample mean of  $y$  using the entire dataset and  $\bar{y}_{(j)}$  is the mean when the  $j$ th observation is omitted, then

$$\bar{y} = \frac{(N-1)\bar{y}_{(j)} + y_j}{N}$$

Solving for  $y_j$ , we obtain

$$y_j = N\bar{y} - (N-1)\bar{y}_{(j)}$$

These are the pseudovalues that `jackknife` calculates. To move this discussion beyond the sample mean, let  $\hat{\theta}$  be the value of our statistic (not necessarily the sample mean) using the entire dataset, and let  $\hat{\theta}_{(j)}$  be the computed value of our statistic with the  $j$ th observation omitted. The pseudovalue for the  $j$ th observation is

$$\hat{\theta}_j^* = N\hat{\theta} - (N-1)\hat{\theta}_{(j)}$$

The mean of the pseudovalues is the alternative, first-order unbiased estimator mentioned above, and the standard error of the mean of the pseudovalues is an estimator for the standard error of  $\hat{\theta}$  (Tukey 1958).

The jackknife estimate of variance has been largely replaced by the bootstrap estimate (see [R] **bootstrap**), which is widely viewed as more efficient and robust. The use of jackknife pseudovalues to detect outliers is too often forgotten and is something the bootstrap does not provide. See Mosteller and Tukey (1977, 133–163) and Mooney and Duval (1993, 22–27) for more information.

## Using jackknife

### Typing

```
. jackknife exp_list: command
```

executes *command* once for each observation in the dataset, leaving the associated observation out of the calculations that make up *exp\_list*.

*command* defines the statistical command to be executed. Most Stata commands and user-written programs can be used with *jackknife*, as long as they follow standard Stata syntax and allow the *if* qualifier; see [U] 11 Language syntax. The *by* prefix may not be part of *command*.

*exp\_list* specifies the statistics to be collected from the execution of *command*. If *command* changes the contents in *e(b)*, *exp\_list* is optional and defaults to *\_b*.

When the *cluster()* option is given, clusters are omitted instead of observations, and *N* is the number of clusters instead of the sample size.

### ► Example 1

As our first example, we will show that the jackknife standard error of the sample mean is equivalent to the standard error of the sample mean computed using the classical formula in the *ci means* command. We use the *double* option to compute the standard errors with the same precision as the *ci means* command.

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. jackknife r(mean), double: summarize mpg
(running summarize on estimation sample)
Jackknife replications (74):10.....20.....30.....40.....
> ...50.....60.....70.... done
Jackknife results Number of obs = 74
 Replications = 74

Command: summarize mpg
 _jk_1: r(mean)
 n(): r(N)
```

|       | Coefficient | Jackknife<br>std. err. | t     | P> t  | [95% conf. interval] |          |
|-------|-------------|------------------------|-------|-------|----------------------|----------|
| _jk_1 | 21.2973     | .6725511               | 31.67 | 0.000 | 19.9569              | 22.63769 |

```
. ci means mpg
```

| Variable | Obs | Mean    | Std. err. | [95% conf. interval] |          |
|----------|-----|---------|-----------|----------------------|----------|
| mpg      | 74  | 21.2973 | .6725511  | 19.9569              | 22.63769 |

## Jackknifed standard deviation

### ▷ Example 2

Mosteller and Tukey (1977, 139–140) request a 95% confidence interval for the standard deviation of the 11 values:

0.1, 0.1, 0.1, 0.4, 0.5, 1.0, 1.1, 1.3, 1.9, 1.9, 4.7

Stata's `summarize` command calculates the mean and standard deviation and stores them as `r(mean)` and `r(sd)`. To obtain the jackknifed standard deviation of the 11 values and save the pseudovalues as a new variable, `sd`, we would type

```
. clear
. input x
 x
 1. 0.1
 2. 0.1
 3. 0.1
 4. 0.4
 5. 0.5
 6. 1.0
 7. 1.1
 8. 1.3
 9. 1.9
10. 1.9
11. 4.7
12. end

. jackknife sd=r(sd), rclass keep: summarize x
(running summarize on estimation sample)
Jackknife replications (11):10. done

Jackknife results Number of obs = 11
 Replications = 11

Command: summarize x
 sd: r(sd)
 n(): r(N)
```

|    | Coefficient | Jackknife<br>std. err. | t    | P> t  | [95% conf. interval] |         |
|----|-------------|------------------------|------|-------|----------------------|---------|
| sd | 1.343469    | .624405                | 2.15 | 0.057 | -.047792             | 2.73473 |

Interpreting the output, the standard deviation reported by `summarize mpg` is 1.34. The jackknife standard error is 0.62. The 95% confidence interval for the standard deviation is  $-0.048$  to  $2.73$ .

By specifying `keep`, `jackknife` creates in our dataset a new variable, `sd`, for the pseudovalues.

```
. list, sep(4)
```

|     | x   | sd       |
|-----|-----|----------|
| 1.  | .1  | 1.139977 |
| 2.  | .1  | 1.139977 |
| 3.  | .1  | 1.139977 |
| 4.  | .4  | .8893147 |
| 5.  | .5  | .824267  |
| 6.  | 1   | .632489  |
| 7.  | 1.1 | .6203189 |
| 8.  | 1.3 | .6218889 |
| 9.  | 1.9 | .835419  |
| 10. | 1.9 | .835419  |
| 11. | 4.7 | 7.703949 |

The jackknife estimate is the average of the `sd` variable, so `sd` contains the individual values of our statistic. We can see that the last observation is substantially larger than the others. The last observation is certainly an outlier, but whether that reflects the considerable information it contains or indicates that it should be excluded from analysis depends on the context of the problem. Mosteller and Tukey created the data by sampling from an exponential distribution, so the observation is informative.

◀

### ▷ Example 3

Let's repeat the example above using the automobile dataset, obtaining the standard error of the standard deviation of `mpg`.

```
. use https://www.stata-press.com/data/r19/auto, clear
(1978 automobile data)
. jackknife sd=r(sd), rclass keep: summarize mpg
(running summarize on estimation sample)
Jackknife replications (74):10.....20.....30.....40.....
> ...50.....60.....70.... done

Jackknife results Number of obs = 74
 Replications = 74

Command: summarize mpg
 sd: r(sd)
 n(): r(N)
```

|    | Coefficient | Jackknife<br>std. err. | t    | P> t  | [95% conf. interval] |          |
|----|-------------|------------------------|------|-------|----------------------|----------|
| sd | 5.785503    | .6072509               | 9.53 | 0.000 | 4.575254             | 6.995753 |

Let's look at sd more carefully:

```
. summarize sd, detail
 pseudovalues: r(sd)

 Percentiles Smallest
 1% 2.870471 2.870471
 5% 2.870471 2.870471
 10% 2.906255 2.870471 Obs 74
 25% 3.328489 2.870471 Sum of wgt. 74
 50% 3.948335 Mean 5.817374
 Largest 5.22377
 75% 6.844418 17.34316 Std. dev. 5.22377
 90% 9.597018 19.7617 Variance 27.28777
 95% 17.34316 19.7617 Skewness 4.07202
 99% 38.60905 38.60905 Kurtosis 23.37823

. list make mpg sd if sd > 30
```

|     | make      | mpg | sd       |
|-----|-----------|-----|----------|
| 71. | VW Diesel | 41  | 38.60905 |

Here the VW Diesel is the only diesel car in our dataset.

## Collecting multiple statistics

### ▷ Example 4

jackknife is not limited to collecting just one statistic. For instance, we can use `summarize`, `detail` and then obtain the jackknife estimate of the standard deviation and skewness. `summarize, detail` stores the standard deviation in `r(sd)` and the skewness in `r(skewness)`, so we might type

```
. use https://www.stata-press.com/data/r19/auto, clear
(1978 automobile data)
. jackknife sd=r(sd) skew=r(skewness), rclass: summarize mpg, detail
(running summarize on estimation sample)
Jackknife replications (74):10.....20.....30.....40.....
> ...50.....60.....70.... done

Jackknife results Number of obs = 74
 Replications = 74

Command: summarize mpg, detail
 sd: r(sd)
 skew: r(skewness)
 n(): r(N)
```

|      | Coefficient | Jackknife<br>std. err. | t    | P> t  | [95% conf. interval] |          |
|------|-------------|------------------------|------|-------|----------------------|----------|
| sd   | 5.785503    | .6072509               | 9.53 | 0.000 | 4.575254             | 6.995753 |
| skew | .9487176    | .3367242               | 2.82 | 0.006 | .2776272             | 1.619808 |

## Collecting coefficients

### ▷ Example 5

jackknife can also collect coefficients from estimation commands. For instance, using `auto.dta`, we might wish to obtain the jackknife standard errors of the coefficients from a regression in which we model the mileage of a car by its weight and trunk space. To do this, we could refer to the coefficients as `_b[weight]`, `_b[trunk]`, `_se[weight]`, and `_se[trunk]` in the `exp_list`, or we could simply use the extended expressions `_b`. In fact, jackknife assumes `_b` by default when used with estimation commands.

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)

. jackknife: regress mpg weight trunk
(running regress on estimation sample)

Jackknife replications (74):10.....20.....30.....40.....
> ...50.....60.....70.... done

Linear regression Number of obs = 74
 Replications = 74
 F(2, 73) = 78.10
 Prob > F = 0.0000
 R-squared = 0.6543
 Adj R-squared = 0.6446
 Root MSE = 3.4492
```

| mpg    | Coefficient | Jackknife<br>std. err. | t     | P> t  | [95% conf. interval] |           |
|--------|-------------|------------------------|-------|-------|----------------------|-----------|
| weight | -.0056527   | .0010216               | -5.53 | 0.000 | -.0076887            | -.0036167 |
| trunk  | -.096229    | .1486236               | -0.65 | 0.519 | -.3924354            | .1999773  |
| _cons  | 39.68913    | 1.873324               | 21.19 | 0.000 | 35.9556              | 43.42266  |

If you are going to use jackknife to estimate standard errors of model coefficients, we recommend using the `vce(jackknife)` option when it is allowed with the estimation command; see [R] [vce\\_option](#).

```
. regress mpg weight trunk, vce(jackknife, nodots)

Linear regression Number of obs = 74
 Replications = 74
 F(2, 73) = 78.10
 Prob > F = 0.0000
 R-squared = 0.6543
 Adj R-squared = 0.6446
 Root MSE = 3.4492
```

| mpg    | Coefficient | Jackknife<br>std. err. | t     | P> t  | [95% conf. interval] |           |
|--------|-------------|------------------------|-------|-------|----------------------|-----------|
| weight | -.0056527   | .0010216               | -5.53 | 0.000 | -.0076887            | -.0036167 |
| trunk  | -.096229    | .1486236               | -0.65 | 0.519 | -.3924354            | .1999773  |
| _cons  | 39.68913    | 1.873324               | 21.19 | 0.000 | 35.9556              | 43.42266  |

## □ Technical note

When the `jackknife` prefix is used with a user-defined program and when the expression list is `_b`, `jackknife` calls

```
set coeftabresults off
```

before entering the replication loop to prevent Stata from performing unnecessary calculations. This means that, provided option `noisily` is not specified, estimation commands will not build or post the coefficient table matrix `r(table)`.

If your program calls an estimation command and needs `r(table)` to exist to perform properly, then your program will need to call

```
set coeftabresults on
```

before calling other estimation commands.

□

**John Wilder Tukey** (1915–2000) was born in Massachusetts. He studied chemistry at Brown and mathematics at Princeton and afterward worked at both Princeton and Bell Labs, as well as being involved in a great many government projects, consultancies, and committees. He made outstanding contributions to several areas of statistics, including time series, multiple comparisons, robust statistics, and exploratory data analysis. Tukey was extraordinarily energetic and inventive, not least in his use of terminology: he is credited with inventing the terms `bit` and `software`, in addition to `ANOVA`, `boxplot`, `data analysis`, `hat matrix`, `jackknife`, `stem-and-leaf plot`, `trimming`, and `winsorizing`, among many others. Tukey's direct and indirect impacts mark him as one of the greatest statisticians of all time.

## Stored results

`jackknife` stores the following in `e()`:

### Scalars

|                           |                                                                        |
|---------------------------|------------------------------------------------------------------------|
| <code>e(N)</code>         | sample size                                                            |
| <code>e(N_reps)</code>    | number of complete replications                                        |
| <code>e(N_misreps)</code> | number of incomplete replications                                      |
| <code>e(N_clust)</code>   | number of clusters                                                     |
| <code>e(k_eq)</code>      | number of equations in <code>e(b)</code>                               |
| <code>e(k_extra)</code>   | number of extra equations                                              |
| <code>e(k_exp)</code>     | number of expressions                                                  |
| <code>e(k_eeexp)</code>   | number of extended expressions ( <code>_b</code> or <code>_se</code> ) |
| <code>e(df_r)</code>      | degrees of freedom                                                     |

### Macros

|                           |                                                                           |

| <code>e(cmd)</code>       | same as <code>e(cmdname)</code> or <code>jackknife</code>                 |
| <code>e(command)</code>   | <i>command</i>                                                            |
| <code>e(cmdline)</code>   | command as typed                                                          |
| <code>e(prefix)</code>    | <code>jackknife</code>                                                    |
| <code>e(wtype)</code>     | weight type                                                               |
| <code>e(wexp)</code>      | weight expression                                                         |
| <code>e(title)</code>     | title in estimation output                                                |
| <code>e(cluster)</code>   | cluster variables                                                         |
| <code>e(pseudo)</code>    | new variables containing pseudovalues                                     |
| <code>e(nfunction)</code> | <code>e(N)</code> , <code>r(N)</code> , <code>n()</code> option, or empty |

|                            |                                  |
|----------------------------|----------------------------------|
| <code>e(exp#)</code>       | expression for the #th statistic |
| <code>e(mse)</code>        | from mse option                  |
| <code>e(vce)</code>        | jackknife                        |
| <code>e(vcetype)</code>    | title used to label Std. err.    |
| <code>e(properties)</code> | b V                              |

#### Matrices

|                              |                                      |
|------------------------------|--------------------------------------|
| <code>e(b)</code>            | observed statistics                  |
| <code>e(b_jk)</code>         | jackknife estimates                  |
| <code>e(V)</code>            | jackknife variance–covariance matrix |
| <code>e(V_modelbased)</code> | model-based variance                 |

In addition to the above, the following is stored in `r()`:

#### Matrices

|                       |                                                                                                                            |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any `r-class` command is run after the estimation command.

When `exp_list` is `_b`, `jackknife` will also carry forward most of the results already in `e()` from *command*.

## Methods and formulas

Let  $\hat{\theta}$  be the observed value of the statistic, that is, the value of the statistic calculated using the original dataset. Let  $\hat{\theta}_{(j)}$  be the value of the statistic computed by leaving out the *j*th observation (or cluster); thus  $j = 1, 2, \dots, N$  identifies an individual observation (or cluster), and *N* is the total number of observations (or clusters). The *j*th pseudo-value is given by

$$\hat{\theta}_j^* = \hat{\theta}_{(j)} + N\{\hat{\theta} - \hat{\theta}_{(j)}\}$$

When the `mse` option is specified, the standard error is estimated as

$$\widehat{\text{se}} = \left\{ \frac{N-1}{N} \sum_{j=1}^N (\hat{\theta}_{(j)} - \hat{\theta})^2 \right\}^{1/2}$$

and the jackknife estimate is

$$\bar{\theta}_{(\cdot)} = \frac{1}{N} \sum_{j=1}^N \hat{\theta}_{(j)}$$

Otherwise, the standard error is estimated as

$$\widehat{\text{se}} = \left\{ \frac{1}{N(N-1)} \sum_{j=1}^N (\hat{\theta}_j^* - \bar{\theta}^*)^2 \right\}^{1/2} \quad \bar{\theta}^* = \frac{1}{N} \sum_{j=1}^N \hat{\theta}_j^*$$

where  $\bar{\theta}^*$  is the jackknife estimate. The variance–covariance matrix is similarly computed.

## Postestimation commands

The following postestimation commands are available after `jackknife`:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| <code>hausman</code>         | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from margins (profile plots, interaction plots, etc.)                                                                 |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | predictions, residuals, influence statistics, and other diagnostic measures                                                             |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

The postestimation command is allowed only if it may be used after *command*.

## predict

The syntax of `predict` (and whether `predict` is even allowed) following `jackknife` depends on the *command* used with `jackknife`.

## margins

The syntax of `margins` (and whether `margins` is even allowed) following `jackknife` depends on the *command* used with `jackknife`.

## Also see

[R] [jackknife](#) — Jackknife estimation

[U] [20 Estimation and postestimation commands](#)

## Description

`kap` and `kappa` calculate the kappa-statistic measure of interrater agreement. `kap` calculates the statistic for two unique raters or at least two nonunique raters. `kappa` calculates only the statistic for nonunique raters, but it handles the case where data have been recorded as rating frequencies. `kapwgt` defines weights used by `kap` in measuring the importance of disagreements.

## Quick start

Calculate interrater agreement for values `rater1` and `rater2`

```
kap rater1 rater2
```

Add table of assessments

```
kap rater1 rater2, tab
```

Same as above, and apply frequency weights defined by `wvar`

```
kap rater1 rater2 [fweight=wvar], tab
```

Agreement for values from three nonunique raters stored in `rater1`, `rater2`, and `rater3`

```
kap rater1 rater2 rater3
```

Add values from an additional three raters stored in `rater4`, `rater5`, and `rater6`

```
kap rater1-rater6
```

Use weights  $1 - |i - j| / (k - 1)$  to weight disagreements between rater 1 and rater 2

```
kap rater1 rater2, wgt(w)
```

Number of times each subject classified in categories stored in `poor`, `fair`, and `good`

```
kappa poor fair good
```

Statistics > Epidemiology and related > Other > Interrater agreement, two unique raters

### kapwgt

Statistics > Epidemiology and related > Other > Define weights for the above (kap)

### kap: nonunique raters

Statistics > Epidemiology and related > Other > Interrater agreement, nonunique raters

### kappa

Statistics > Epidemiology and related > Other > Interrater agreement, nonunique raters with frequencies

## Syntax

*Interrater agreement, two unique raters*

```
kap varname1 varname2 [if] [in] [weight] [, options]
```

*Weights for weighting disagreements*

```
kapwgt wgtid [1 \ # 1 [\ # # 1 ...]]
```

*Interrater agreement, nonunique raters, variables record ratings for each rater*

```
kap varname1 varname2 varname3 [...] [if] [in] [weight]
```

*Interrater agreement, nonunique raters, variables record frequency of ratings*

```
kappa varlist [if] [in]
```

*options*

Description

---

|                          |                                                                                   |
|--------------------------|-----------------------------------------------------------------------------------|
| Main                     |                                                                                   |
| <code>tab</code>         | display table of assessments                                                      |
| <code>wgt (wgtid)</code> | specify how to weight disagreements; see <a href="#">Options</a> for alternatives |
| <code>absolute</code>    | treat rating categories as absolute                                               |

---

`collect` is allowed with `kap` and `kappa`; see [\[U\] 11.1.10 Prefix commands](#).

`fweights` are allowed; see [\[U\] 11.1.6 weight](#).

## Options

Main

`tab` displays a tabulation of the assessments by the two raters.

`wgt(wgtid)` specifies that `wgtid` be used to weight disagreements. You can define your own weights by using `kapwgt`; `wgt()` then specifies the name of the user-defined matrix. For instance, you might define

```
. kapwgt mine 1 \ .8 1 \ 0 .8 1 \ 0 0 .8 1
```

and then

```
. kap rata ratb, wgt(mine)
```

Also, two prerecorded weights are available.

`wgt(w)` specifies weights  $1 - |i - j| / (k - 1)$ , where  $i$  and  $j$  index the rows and columns of the ratings by the two raters and  $k$  is the maximum number of possible ratings.

`wgt(w2)` specifies weights  $1 - \{(i - j) / (k - 1)\}^2$ .

`absolute` is relevant only if `wgt()` is also specified. The `absolute` option modifies how  $i$ ,  $j$ , and  $k$  are defined and how corresponding entries are found in a user-defined weighting matrix. When `absolute` is not specified,  $i$  and  $j$  refer to the row and column index, not to the ratings themselves. Say that the ratings are recorded as  $\{0, 1, 1.5, 2\}$ . There are four ratings;  $k = 4$ , and  $i$  and  $j$  are still 1, 2, 3, and 4 in the formulas above. Index 3, for instance, corresponds to rating = 1.5. This system is convenient but can, with some data, lead to difficulties.

When `absolute` is specified, all ratings must be integers, and they must be coded from the set  $\{1, 2, 3, \dots\}$ . Not all values need be used; integer values that do not occur are simply assumed to be unobserved.

## Remarks and examples

Remarks are presented under the following headings:

*Two raters*

*More than two raters*

The kappa-statistic measure of agreement is scaled to be 0 when the amount of agreement is what would be expected to be observed by chance and 1 when there is perfect agreement. For intermediate values, Landis and Koch (1977a, 165) suggest the following interpretations:

|           |                |
|-----------|----------------|
| below 0.0 | Poor           |
| 0.00–0.20 | Slight         |
| 0.21–0.40 | Fair           |
| 0.41–0.60 | Moderate       |
| 0.61–0.80 | Substantial    |
| 0.81–1.00 | Almost perfect |

## Two raters

### ▷ Example 1

Consider the classification by two radiologists of 85 xeromammograms as normal, benign disease, suspicion of cancer, or cancer (a subset of the data from Boyd et al. [1982] and discussed in the context of kappa in Altman [1991, 403–405]).

```
. use https://www.stata-press.com/data/r19/rate2
(Altman p. 403)
. tabulate rada radb
```

| Radiologist<br>A's<br>assessment | Radiologist B's assessment |        |         |        | Total |
|----------------------------------|----------------------------|--------|---------|--------|-------|
|                                  | Normal                     | Benign | Suspect | Cancer |       |
| Normal                           | 21                         | 12     | 0       | 0      | 33    |
| Benign                           | 4                          | 17     | 1       | 0      | 22    |
| Suspect                          | 3                          | 9      | 15      | 2      | 29    |
| Cancer                           | 0                          | 0      | 0       | 1      | 1     |
| Total                            | 28                         | 38     | 16      | 3      | 85    |

Our dataset contains two variables: rada, radiologist A's assessment, and radb, radiologist B's assessment. Each observation is a patient.

We can obtain the kappa measure of interrater agreement by typing

```
. kap rada radb
```

| Agreement | Expected<br>agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|-----------------------|--------|-----------|------|--------|
| 63.53%    | 30.82%                | 0.4728 | 0.0694    | 6.81 | 0.0000 |

If each radiologist had made his determination randomly (but with probabilities equal to the overall proportions), we would expect the two radiologists to agree on 30.8% of the patients. In fact, they agreed on 63.5% of the patients, or 47.3% of the way between random agreement and perfect agreement. The amount of agreement indicates that we can reject the hypothesis that they are making their determinations randomly.

### ▷ Example 2: Weighted kappa, prerecorded weight $w$

There is a difference between two radiologists disagreeing about whether a xeromammogram indicates cancer or the suspicion of cancer and disagreeing about whether it indicates cancer or is normal. The weighted kappa attempts to deal with this. `kap` provides two “prerecorded” weights,  $w$  and  $w2$ :

```
. kap rada radb, wgt(w)
Ratings weighted by:
 1.0000 0.6667 0.3333 0.0000
 0.6667 1.0000 0.6667 0.3333
 0.3333 0.6667 1.0000 0.6667
 0.0000 0.3333 0.6667 1.0000
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 86.67%    | 69.11%             | 0.5684 | 0.0788    | 7.22 | 0.0000 |

The  $w$  weights are given by  $1 - |i - j| / (k - 1)$ , where  $i$  and  $j$  index the rows of columns of the ratings by the two raters and  $k$  is the maximum number of possible ratings. The weighting matrix is printed above the table. Here the rows and columns of the  $4 \times 4$  matrix correspond to the ratings normal, benign, suspicious, and cancerous.

A weight of 1 indicates that an observation should count as perfect agreement. The matrix has 1s down the diagonals—when both radiologists make the same assessment, they are in agreement. A weight of, say, 0.6667 means that they are in two-thirds agreement. In our matrix, they get that score if they are “one apart”—one radiologist assesses cancer and the other is merely suspicious, or one is suspicious and the other says benign, and so on. An entry of 0.3333 means that they are in one-third agreement, or, if you prefer, two-thirds disagreement. That is the score attached when they are “two apart”. Finally, they are in complete disagreement when the weight is zero, which happens only when they are three apart—one says cancer and the other says normal.

◀

### ▷ Example 3: Weighted kappa, prerecorded weight $w2$

The other prerecorded weight is  $w2$ , where the weights are given by  $1 - \{(i - j) / (k - 1)\}^2$ :

```
. kap rada radb, wgt(w2)
Ratings weighted by:
 1.0000 0.8889 0.5556 0.0000
 0.8889 1.0000 0.8889 0.5556
 0.5556 0.8889 1.0000 0.8889
 0.0000 0.5556 0.8889 1.0000
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 94.77%    | 84.09%             | 0.6714 | 0.1079    | 6.22 | 0.0000 |

The  $w2$  weight makes the categories even more alike and is probably inappropriate here.

◀

### ► Example 4: Weighted kappa, user-defined weights

In addition to using prerecorded weights, we can define our own weights with the `kapwgt` command. For instance, we might feel that suspicious and cancerous are reasonably similar, that benign and normal are reasonably similar, but that the suspicious/cancerous group is nothing like the benign/normal group:

```
. kapwgt xm 1 \ .8 1 \ 0 0 1 \ 0 0 .8 1
. kapwgt xm
1.0000
0.8000 1.0000
0.0000 0.0000 1.0000
0.0000 0.0000 0.8000 1.0000
```

We name the weights `xm`, and after the weight name, we enter the lower triangle of the weighting matrix, using `\` to separate rows. We have four outcomes, so we continued entering numbers until we had defined the fourth row of the weighting matrix. If we type `kapwgt` followed by a name and nothing else, it shows us the weights recorded under that name. Satisfied that we have entered them correctly, we now use the weights to recalculate kappa:

```
. kap rada radb, wgt(xm)
Ratings weighted by:
 1.0000 0.8000 0.0000 0.0000
 0.8000 1.0000 0.0000 0.0000
 0.0000 0.0000 1.0000 0.8000
 0.0000 0.0000 0.8000 1.0000
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 80.47%    | 52.67%             | 0.5874 | 0.0865    | 6.79 | 0.0000 |

◀

### □ Technical note

In addition to using weights for weighting the differences in categories, you can specify Stata's traditional weights for weighting the data. In the examples above, we have 85 observations in our dataset—one for each patient. If we only knew the table of outcomes—that there were 21 patients rated normal by both radiologists, etc.—it would be easier to enter the table into Stata and work from it. The easiest way to enter the data is with `tabi`; see [\[R\] tabulate twoway](#).

```
. tabi 21 12 0 0 \ 4 17 1 0 \ 3 9 15 2 \ 0 0 0 1, replace
```

| row   | col |    |    |   | Total |
|-------|-----|----|----|---|-------|
|       | 1   | 2  | 3  | 4 |       |
| 1     | 21  | 12 | 0  | 0 | 33    |
| 2     | 4   | 17 | 1  | 0 | 22    |
| 3     | 3   | 9  | 15 | 2 | 29    |
| 4     | 0   | 0  | 0  | 1 | 1     |
| Total | 28  | 38 | 16 | 3 | 85    |

Pearson chi2(9) = 77.8111 Pr = 0.000

tabi reported the Pearson  $\chi^2$  for this table, but we do not care about it. The important thing is that, with the `replace` option, tabi left the table in memory:

```
. list in 1/5
```

|    | row | col | pop |
|----|-----|-----|-----|
| 1. | 1   | 1   | 21  |
| 2. | 1   | 2   | 12  |
| 3. | 1   | 3   | 0   |
| 4. | 1   | 4   | 0   |
| 5. | 2   | 1   | 4   |

The variable `row` is radiologist A's assessment, `col` is radiologist B's assessment, and `pop` is the number so assessed by both. Thus,

```
. kap row col [fweight=pop]
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 63.53%    | 30.82%             | 0.4728 | 0.0694    | 6.81 | 0.0000 |

If we are going to keep these data, the names `row` and `col` are not indicative of what the data reflect. We could type (see [U] 12.6 **Dataset, variable, and value labels**)

```
. rename row rada
. rename col radb
. label var rada "Radiologist A's assessment"
. label var radb "Radiologist B's assessment"
. label define assess 1 normal 2 benign 3 suspect 4 cancer
. label values rada assess
. label values radb assess
. label data "Altman, page 403"
```

`kap`'s `tab` option, which can be used with or without weighted data, shows the table of assessments:

```
. kap rada radb [fweight=pop], tab
```

| Radiologist A's assessment | Radiologist B's assessment |        |         |        | Total |
|----------------------------|----------------------------|--------|---------|--------|-------|
|                            | normal                     | benign | suspect | cancer |       |
| normal                     | 21                         | 12     | 0       | 0      | 33    |
| benign                     | 4                          | 17     | 1       | 0      | 22    |
| suspect                    | 3                          | 9      | 15      | 2      | 29    |
| cancer                     | 0                          | 0      | 0       | 1      | 1     |
| Total                      | 28                         | 38     | 16      | 3      | 85    |

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 63.53%    | 30.82%             | 0.4728 | 0.0694    | 6.81 | 0.0000 |

## □ Technical note

You have data on individual patients. There are two raters, and the possible ratings are 1, 2, 3, and 4, but neither rater ever used rating 3:

```
. use https://www.stata-press.com/data/r19/rate2no3, clear
. tabulate ratera raterb
```

| Rater A | Rater B |   |    | Total |
|---------|---------|---|----|-------|
|         | 1       | 2 | 4  |       |
| 1       | 6       | 4 | 3  | 13    |
| 2       | 5       | 3 | 3  | 11    |
| 4       | 1       | 1 | 26 | 28    |
| Total   | 12      | 8 | 32 | 52    |

Here `kap` would determine that the ratings are from the set  $\{1, 2, 4\}$  because those were the only values observed. `kap` would expect a user-defined weighting matrix to be  $3 \times 3$ , and if it were not, `kap` would issue an error message. In the formula-based weights, the calculation would be based on  $i, j = 1, 2, 3$  corresponding to the three observed ratings  $\{1, 2, 4\}$ .

Specifying the `absolute` option would clarify that the ratings are 1, 2, 3, and 4; it just so happens that rating 3 was never assigned. If a user-defined weighting matrix were also specified, `kap` would expect it to be  $4 \times 4$  or larger (larger because we can think of the ratings being 1, 2, 3, 4, 5, ... and it just so happens that ratings 5, 6, ... were never observed, just as rating 3 was not observed). In the formula-based weights, the calculation would be based on  $i, j = 1, 2, 4$ .

```
. kap ratera raterb, wgt(w)
```

Ratings weighted by:

```
1.0000 0.5000 0.0000
0.5000 1.0000 0.5000
0.0000 0.5000 1.0000
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 79.81%    | 57.17%             | 0.5285 | 0.1169    | 4.52 | 0.0000 |

```
. kap ratera raterb, wgt(w) absolute
```

Ratings weighted by:

```
1.0000 0.6667 0.0000
0.6667 1.0000 0.3333
0.0000 0.3333 1.0000
```

| Agreement | Expected agreement | Kappa  | Std. err. | Z    | Prob>Z |
|-----------|--------------------|--------|-----------|------|--------|
| 81.41%    | 55.08%             | 0.5862 | 0.1209    | 4.85 | 0.0000 |

If all conceivable ratings are observed in the data, specifying `absolute` makes no difference. For instance, if rater A assigns ratings  $\{1, 2, 4\}$  and rater B assigns  $\{1, 2, 3, 4\}$ , the complete set of assigned ratings is  $\{1, 2, 3, 4\}$ , the same that `absolute` would specify. Without `absolute`, it makes no difference whether the ratings are coded  $\{1, 2, 3, 4\}$ ,  $\{0, 1, 2, 3\}$ ,  $\{1, 7, 9, 100\}$ ,  $\{0, 1, 1.5, 2.0\}$ , or otherwise.

□

## More than two raters

For more than two raters, the mathematics are such that the two raters are not considered unique. For instance, if there are three raters, there is no assumption that the three raters who rate the first subject are the same as the three raters who rate the second. Although we call this the “more than two raters” case, it can be used with two raters when the raters’ identities vary.

The nonunique rater case can be usefully broken down into three subcases: 1) there are two possible ratings, which we will call positive and negative; 2) there are more than two possible ratings, but the number of raters per subject is the same for all subjects; and 3) there are more than two possible ratings, and the number of raters per subject varies. `kappa` handles all these cases. To emphasize that there is no assumption of constant identity of raters across subjects, the variables specified contain counts of the number of raters rating the subject into a particular category.

Jacob Cohen (1923–1998) was born in New York City. After studying psychology at City College of New York and New York University, he worked as a medical psychologist until 1959 when he became a full professor in the Department of Psychology at New York University. He made many contributions to research methods, including the kappa measure. He persistently emphasized the value of multiple regression and the importance of power and of measuring effects rather than testing significance.

### ► Example 5: Two ratings

Fleiss, Levin, and Paik (2003, 612) offer the following hypothetical ratings by different sets of raters on 25 subjects:

| Subject | No. of raters | No. of pos. ratings | Subject | No. of raters | No. of pos. ratings |
|---------|---------------|---------------------|---------|---------------|---------------------|
| 1       | 2             | 2                   | 14      | 4             | 3                   |
| 2       | 2             | 0                   | 15      | 2             | 0                   |
| 3       | 3             | 2                   | 16      | 2             | 2                   |
| 4       | 4             | 3                   | 17      | 3             | 1                   |
| 5       | 3             | 3                   | 18      | 2             | 1                   |
| 6       | 4             | 1                   | 19      | 4             | 1                   |
| 7       | 3             | 0                   | 20      | 5             | 4                   |
| 8       | 5             | 0                   | 21      | 3             | 2                   |
| 9       | 2             | 0                   | 22      | 4             | 0                   |
| 10      | 4             | 4                   | 23      | 3             | 0                   |
| 11      | 5             | 5                   | 24      | 3             | 3                   |
| 12      | 3             | 3                   | 25      | 2             | 2                   |
| 13      | 4             | 4                   |         |               |                     |

We have entered these data into Stata, and the variables are called `subject`, `raters`, and `pos`. `kappa`, however, requires that we specify variables containing the number of positive ratings and negative ratings, that is, `pos` and `raters-pos`:

```
. use https://www.stata-press.com/data/r19/p612
. generate neg = raters-pos
. kappa pos neg
```

Two-outcomes, multiple raters:

| Kappa  | Z    | Prob>Z |
|--------|------|--------|
| 0.5415 | 5.28 | 0.0000 |

We would have obtained the same results if we had typed `kappa neg pos`.

▷ **Example 6: More than two ratings, constant number of raters, kappa**

Each of 10 subjects is rated into one of three categories by five raters (Fleiss, Levin, and Paik 2003, 615):

```
. use https://www.stata-press.com/data/r19/p615, clear
. list
```

|     | subject | cat1 | cat2 | cat3 |
|-----|---------|------|------|------|
| 1.  | 1       | 1    | 4    | 0    |
| 2.  | 2       | 2    | 0    | 3    |
| 3.  | 3       | 0    | 0    | 5    |
| 4.  | 4       | 4    | 0    | 1    |
| 5.  | 5       | 3    | 0    | 2    |
| 6.  | 6       | 1    | 4    | 0    |
| 7.  | 7       | 5    | 0    | 0    |
| 8.  | 8       | 0    | 4    | 1    |
| 9.  | 9       | 1    | 0    | 4    |
| 10. | 10      | 3    | 0    | 2    |

We obtain the kappa statistic:

```
. kappa cat1-cat3
```

| Outcome    | Kappa  | Z    | Prob>Z |
|------------|--------|------|--------|
| Category 1 | 0.2917 | 2.92 | 0.0018 |
| Category 2 | 0.6711 | 6.71 | 0.0000 |
| Category 3 | 0.3490 | 3.49 | 0.0002 |
| combined   | 0.4179 | 5.83 | 0.0000 |

The first part of the output shows the results of calculating kappa for each of the categories separately against an amalgam of the remaining categories. For instance, the `cat1` line is the two-rating kappa, where positive is `cat1` and negative is `cat2` or `cat3`. The test statistic, however, is calculated differently (see *Methods and formulas*). The combined kappa is the appropriately weighted average of the individual kappas. There is considerably less agreement about the rating of subjects into the first category than there is for the second.

▷ Example 7: More than two ratings, constant number of raters, kap

Now, suppose that we have the same data as in the previous example but that the data are organized differently:

```
. use https://www.stata-press.com/data/r19/p615b
. list
```

|     | subject | rater1 | rater2 | rater3 | rater4 | rater5 |
|-----|---------|--------|--------|--------|--------|--------|
| 1.  | 1       | 1      | 2      | 2      | 2      | 2      |
| 2.  | 2       | 1      | 1      | 3      | 3      | 3      |
| 3.  | 3       | 3      | 3      | 3      | 3      | 3      |
| 4.  | 4       | 1      | 1      | 1      | 1      | 3      |
| 5.  | 5       | 1      | 1      | 1      | 3      | 3      |
| 6.  | 6       | 1      | 2      | 2      | 2      | 2      |
| 7.  | 7       | 1      | 1      | 1      | 1      | 1      |
| 8.  | 8       | 2      | 2      | 2      | 2      | 3      |
| 9.  | 9       | 1      | 3      | 3      | 3      | 3      |
| 10. | 10      | 1      | 1      | 1      | 3      | 3      |

Here we would use `kap` rather than `kappa` because the variables record ratings for each rater.

```
. kap rater1 rater2 rater3 rater4 rater5
```

There are 5 raters per subject:

| Outcome  | Kappa  | Z    | Prob>Z |
|----------|--------|------|--------|
| 1        | 0.2917 | 2.92 | 0.0018 |
| 2        | 0.6711 | 6.71 | 0.0000 |
| 3        | 0.3490 | 3.49 | 0.0002 |
| combined | 0.4179 | 5.83 | 0.0000 |

It does not matter which rater is which when there are more than two raters.

▷ Example 8: More than two ratings, varying number of raters, kappa

In this unfortunate case, kappa can be calculated, but there is no test statistic for testing against  $\kappa > 0$ . We do nothing differently—kappa calculates the total number of raters for each subject, and, if it is not a constant, kappa suppresses the calculation of test statistics.

```
. use https://www.stata-press.com/data/r19/rvary
. list
```

|     | subject | cat1 | cat2 | cat3 |
|-----|---------|------|------|------|
| 1.  | 1       | 1    | 3    | 0    |
| 2.  | 2       | 2    | 0    | 3    |
| 3.  | 3       | 0    | 0    | 5    |
| 4.  | 4       | 4    | 0    | 1    |
| 5.  | 5       | 3    | 0    | 2    |
| 6.  | 6       | 1    | 4    | 0    |
| 7.  | 7       | 5    | 0    | 0    |
| 8.  | 8       | 0    | 4    | 1    |
| 9.  | 9       | 1    | 0    | 2    |
| 10. | 10      | 3    | 0    | 2    |

```
. kappa cat1-cat3
```

| Outcome    | Kappa  | Z | Prob>Z |
|------------|--------|---|--------|
| Category 1 | 0.2685 | . | .      |
| Category 2 | 0.6457 | . | .      |
| Category 3 | 0.2938 | . | .      |
| combined   | 0.3816 | . | .      |

Note: Number of ratings per subject vary; cannot calculate test statistics.

◀

▷ Example 9: More than two ratings, varying number of raters, kap

This case is similar to the [previous example](#), but the data are organized differently:

```
. use https://www.stata-press.com/data/r19/rvary2
. list
```

|     | subject | rater1 | rater2 | rater3 | rater4 | rater5 |
|-----|---------|--------|--------|--------|--------|--------|
| 1.  | 1       | 1      | 2      | 2      | .      | 2      |
| 2.  | 2       | 1      | 1      | 3      | 3      | 3      |
| 3.  | 3       | 3      | 3      | 3      | 3      | 3      |
| 4.  | 4       | 1      | 1      | 1      | 1      | 3      |
| 5.  | 5       | 1      | 1      | 1      | 3      | 3      |
| 6.  | 6       | 1      | 2      | 2      | 2      | 2      |
| 7.  | 7       | 1      | 1      | 1      | 1      | 1      |
| 8.  | 8       | 2      | 2      | 2      | 2      | 3      |
| 9.  | 9       | 1      | 3      | .      | .      | 3      |
| 10. | 10      | 1      | 1      | 1      | 3      | 3      |

Here we specify kap instead of kappa because the variables record ratings for each rater.

```
. kap rater1-rater5
```

There are between 3 and 5 (median = 5.00) raters per subject:

| Outcome  | Kappa  | Z | Prob>Z |
|----------|--------|---|--------|
| 1        | 0.2685 | . | .      |
| 2        | 0.6457 | . | .      |
| 3        | 0.2938 | . | .      |
| combined | 0.3816 | . | .      |

Note: Number of ratings per subject vary; cannot calculate test statistics.

◀

## Stored results

kap and kappa store the following in `r()`:

Scalars

|                        |                                             |                       |                                    |
|------------------------|---------------------------------------------|-----------------------|------------------------------------|
| <code>r(N)</code>      | number of subjects (kap only)               | <code>r(kappa)</code> | kappa                              |
| <code>r(prop_o)</code> | observed proportion of agreement (kap only) | <code>r(z)</code>     | z statistic                        |
| <code>r(prop_e)</code> | expected proportion of agreement (kap only) | <code>r(se)</code>    | standard error for kappa statistic |

## Methods and formulas

The kappa statistic was first proposed by [Cohen \(1960\)](#). The generalization for weights reflecting the relative seriousness of each possible disagreement is due to [Cohen \(1968\)](#). The analysis-of-variance approach for  $k = 2$  and  $m \geq 2$  is due to [Landis and Koch \(1977b\)](#). See [Altman \(1991, 403–409\)](#) or [Dunn \(2000, chap. 2\)](#) for an introductory treatment and [Fleiss, Levin, and Paik \(2003, chap. 18\)](#) for a more detailed treatment. All formulas below are as presented in [Fleiss, Levin, and Paik \(2003\)](#). Let  $m$  be the number of raters, and let  $k$  be the number of rating outcomes.

Methods and formulas are presented under the following headings:

*kap*:  $m = 2$

*kappa*:  $m > 2, k = 2$

*kappa*:  $m > 2, k > 2$

**kap: m = 2**

Define  $w_{ij}$  ( $i = 1, \dots, k$  and  $j = 1, \dots, k$ ) as the weights for agreement and disagreement ( $\text{wgt}()$ ), or, if the data are not weighted, define  $w_{ii} = 1$  and  $w_{ij} = 0$  for  $i \neq j$ . If  $\text{wgt}(w)$  is specified,  $w_{ij} = 1 - |i - j|/(k - 1)$ . If  $\text{wgt}(w2)$  is specified,  $w_{ij} = 1 - \{(i - j)/(k - 1)\}^2$ .

The observed proportion of agreement is

$$p_o = \sum_{i=1}^k \sum_{j=1}^k w_{ij} p_{ij}$$

where  $p_{ij}$  is the fraction of ratings  $i$  by the first rater and  $j$  by the second. The expected proportion of agreement is

$$p_e = \sum_{i=1}^k \sum_{j=1}^k w_{ij} p_{i \cdot} p_{\cdot j}$$

where  $p_{i \cdot} = \sum_j p_{ij}$  and  $p_{\cdot j} = \sum_i p_{ij}$ .

Kappa is given by  $\hat{\kappa} = (p_o - p_e)/(1 - p_e)$ .

The standard error of  $\hat{\kappa}$  for testing against 0 is

$$\hat{\sigma}_0 = \frac{1}{(1 - p_e)\sqrt{n}} \left( \left[ \sum_i \sum_j p_{i \cdot} p_{\cdot j} \{w_{ij} - (\bar{w}_i + \bar{w}_j)\}^2 \right] - p_e^2 \right)^{1/2}$$

where  $n$  is the number of subjects being rated,  $\bar{w}_i = \sum_j p_{\cdot j} w_{ij}$ , and  $\bar{w}_j = \sum_i p_i w_{ij}$ . The test statistic  $Z = \hat{\kappa}/\hat{\sigma}_0$  is assumed to be distributed  $N(0, 1)$ .

**kappa: m > 2, k = 2**

Each subject  $i$ ,  $i = 1, \dots, n$ , is found by  $x_i$  of  $m_i$  raters to be positive (the choice as to what is labeled positive is arbitrary).

The overall proportion of positive ratings is  $\bar{p} = \sum_i x_i/(n\bar{m})$ , where  $\bar{m} = \sum_i m_i/n$ . The between-subjects mean square is (approximately)

$$B = \frac{1}{n} \sum_i \frac{(x_i - m_i \bar{p})^2}{m_i}$$

and the within-subject mean square is

$$W = \frac{1}{n(\bar{m} - 1)} \sum_i \frac{x_i(m_i - x_i)}{m_i}$$

Kappa is then defined as

$$\hat{\kappa} = \frac{B - W}{B + (\bar{m} - 1)W}$$

The standard error for testing against 0 (Fleiss and Cuzick 1979) is approximately equal to and is calculated as

$$\hat{s}_0 = \frac{1}{(\bar{m} - 1)\sqrt{n\bar{m}_H}} \left\{ 2(\bar{m}_H - 1) + \frac{(\bar{m} - \bar{m}_H)(1 - 4\bar{p}\bar{q})}{\bar{m}\bar{p}\bar{q}} \right\}^{1/2}$$

where  $\bar{m}_H$  is the harmonic mean of  $m_i$  and  $\bar{q} = 1 - \bar{p}$ .

The test statistic  $Z = \hat{\kappa}/\hat{s}_0$  is assumed to be distributed  $N(0, 1)$ .

### kappa: $m > 2, k > 2$

Let  $x_{ij}$  be the number of ratings on subject  $i, i = 1, \dots, n$ , into category  $j, j = 1, \dots, k$ . Define  $\bar{p}_j$  as the overall proportion of ratings in category  $j, \bar{q}_j = 1 - \bar{p}_j$ , and let  $\hat{\kappa}_j$  be the kappa statistic given above for  $k = 2$  when category  $j$  is compared with the amalgam of all other categories. Kappa is

$$\bar{\kappa} = \frac{\sum_j \bar{p}_j \bar{q}_j \hat{\kappa}_j}{\sum_j \bar{p}_j \bar{q}_j}$$

(Landis and Koch 1977b). In the case where the number of raters per subject,  $\sum_j x_{ij}$ , is a constant  $m$  for all  $i$ , Fleiss, Nee, and Landis (1979) derived the following formulas for the approximate standard errors. The standard error for testing  $\hat{\kappa}_j$  against 0 is

$$\hat{s}_j = \left\{ \frac{2}{nm(m-1)} \right\}^{1/2}$$

and the standard error for testing  $\bar{\kappa}$  is

$$\bar{s} = \frac{\sqrt{2}}{\sum_j \bar{p}_j \bar{q}_j \sqrt{nm(m-1)}} \left\{ \left( \sum_j \bar{p}_j \bar{q}_j \right)^2 - \sum_j \bar{p}_j \bar{q}_j (\bar{q}_j - \bar{p}_j) \right\}^{1/2}$$

## Description

`kdensity` produces kernel density estimates and graphs the result.

## Quick start

Graph of the kernel density estimate for `v1`

```
kdensity v1
```

Add a normal curve

```
kdensity v1, normal
```

With a kernel bandwidth of 2

```
kdensity v1, bwidth(2)
```

Gaussian kernel function for `v1`

```
kdensity v1, kernel(gaussian)
```

Kernel density estimate for `v1` and `v2` in the same graph area

```
twoway kdensity v1 || kdensity v2
```

Separate graphs of kernel density estimate of `v1` for each level of `catvar`

```
twoway kdensity v1, by(catvar)
```

Kernel density estimates of `v1` for `catvar = 0` and `1` in the same graph area

```
twoway kdensity v1 if catvar==0 || kdensity v1 if catvar==1
```

fweights, aweights, and iweights are allowed; see [U] 11.1.6 weight.

## Options

### Main

`kernel` (*kernel*) specifies the kernel function for use in calculating the kernel density estimate. The default kernel is the Epanechnikov kernel (`epanechnikov`).

`bw`width(*#*) specifies the half-width of the kernel, the width of the density window around each point. If `bw`width() is not specified, the “optimal” width is calculated and used. The optimal width is the width that would minimize the mean integrated squared error if the data were Gaussian and a Gaussian kernel were used, so it is not optimal in any global sense. In fact, for multimodal and highly skewed densities, this width is usually too wide and oversmooths the density (Silverman 1986).

`generate` (*newvar<sub>x</sub>* *newvar<sub>d</sub>*) stores the results of the estimation. *newvar<sub>x</sub>* will contain the points at which the density is estimated. *newvar<sub>d</sub>* will contain the density estimate.

`n`(*#*) specifies the number of points at which the density estimate is to be evaluated. The default is  $\min(N, 50)$ , where  $N$  is the number of observations in memory.

`at` (*var<sub>x</sub>*) specifies a variable that contains the values at which the density should be estimated. This option allows you to more easily obtain density estimates for different variables or different subsamples of a variable and then overlay the estimated densities for comparison.

`nograph` suppresses the graph. This option is often used with the `generate` () option.

### Kernel plot

`cline_options` affect the rendition of the plotted kernel density estimate. See [G-3] *cline\_options*.

### Density plots

`normal` requests that a normal density be overlaid on the density estimate for comparison.

`normopts` (*cline\_options*) specifies details about the rendition of the normal curve, such as the color and style of line used. See [G-3] *cline\_options*.

`student` (*#*) specifies that a Student’s  $t$  density with  $\#$  degrees of freedom be overlaid on the density estimate for comparison.

`stopts` (*cline\_options*) affects the rendition of the Student’s  $t$  density. See [G-3] *cline\_options*.

### Add plots

`addplot` (*plot*) provides a way to add other plots to the generated graph. See [G-3] *addplot\_option*.

### Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] *twoway\_options*, excluding `by` (). These include options for titling the graph (see [G-3] *title\_options*) and for saving the graph to disk (see [G-3] *saving\_option*).

## Remarks and examples

Kernel density estimators approximate the density  $f(x)$  from observations on  $x$ . Histograms do this, too, and the histogram itself is a kind of kernel density estimate. The data are divided into nonoverlapping intervals, and counts are made of the number of data points within each interval. Histograms are bar graphs that depict these frequency counts—the bar is centered at the midpoint of each interval—and its height reflects the average number of data points in the interval.

In more general kernel density estimates, the range is still divided into intervals, and estimates of the density at the center of intervals are produced. One difference is that the intervals are allowed to overlap. We can think of sliding the interval—called a window—along the range of the data and collecting the center-point density estimates. The second difference is that, rather than merely counting the number of observations in a window, a kernel density estimator assigns a weight between 0 and 1—based on the distance from the center of the window—and sums the weighted values. The function that determines these weights is called the kernel.

Kernel density estimates have the advantages of being smooth and of being independent of the choice of origin (corresponding to the location of the bins in a histogram).

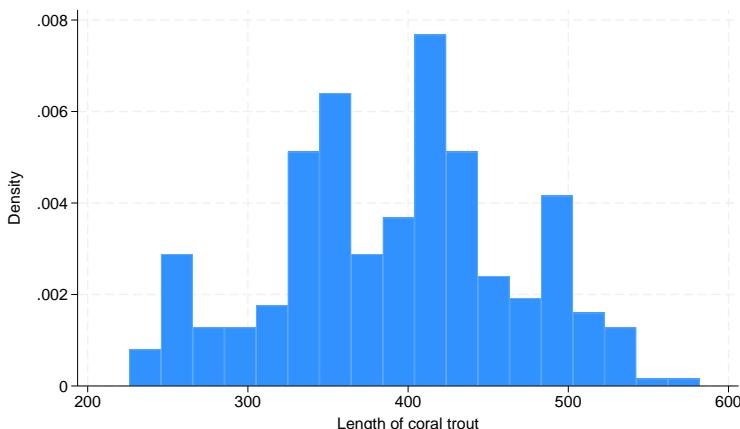

See [Salgado-Ugarte, Shimizu, and Taniuchi \(1993\)](#) and [Fox \(1990\)](#) for discussions of kernel density estimators that stress their use as exploratory data-analysis tools.

[Cox \(2007\)](#) gives a lucid introductory tutorial on kernel density estimation with several Stata produced examples. He provides tips and tricks for working with skewed or bounded distributions and applying the same techniques to estimate the intensity function of a point process.

### ▷ Example 1: Histogram and kernel density estimate

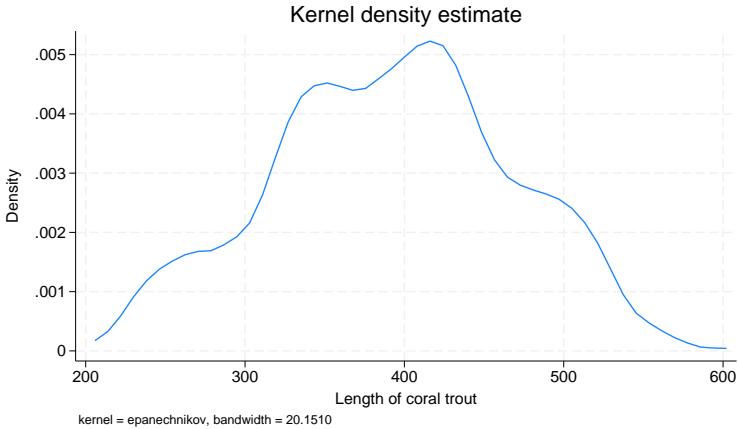

[Goeden \(1978\)](#) reports data consisting of 316 length observations of coral trout. We wish to investigate the underlying density of the lengths. To begin on familiar ground, we might draw a histogram. In [\[R\] histogram](#), we suggest setting the bins to  $\min(\sqrt{n}, 10 \cdot \log_{10} n)$ , which for  $n = 316$  is roughly 18:

```
. use https://www.stata-press.com/data/r19/trocolen
. histogram length, bins(18)
(bin=18, start=226, width=19.777778)
```

The kernel density estimate, on the other hand, is smooth.

```
. kdensity length
```

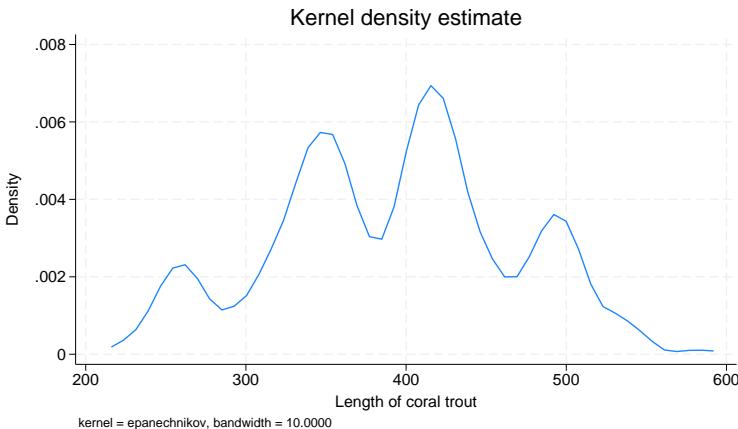

Kernel density estimators are, however, sensitive to an assumption, just as are histograms. In histograms, we specify a number of bins. For kernel density estimators, we specify a width. In the graph above, we used the default width. `kdensity` is smarter than `twoway histogram` in that its default width is not a fixed constant. Even so, the default width is not necessarily best.

`kdensity` stores the width in the returned scalar `bwidth`, so typing `display r(bwidth)` reveals it. Doing this, we discover that the width is approximately 20.

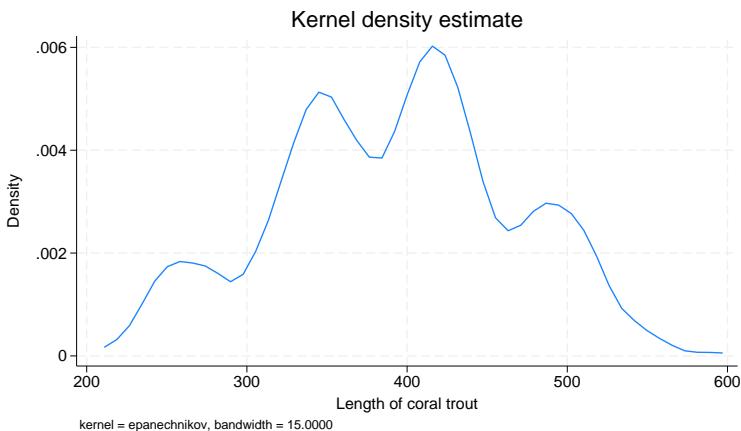

Widths are similar to the inverse of the number of bins in a histogram in that smaller widths provide more detail. The units of the width are the units of  $x$ , the variable being analyzed. The width is specified as a half-width, meaning that the kernel density estimator with half-width 20 corresponds to sliding a window of size 40 across the data.

We can specify half-widths for ourselves by using the `bwidth()` option. Smaller widths do not smooth the density as much:

```
. kdensity length, bwidth(10)
```

```
. kdensity length, bwidth(15)
```

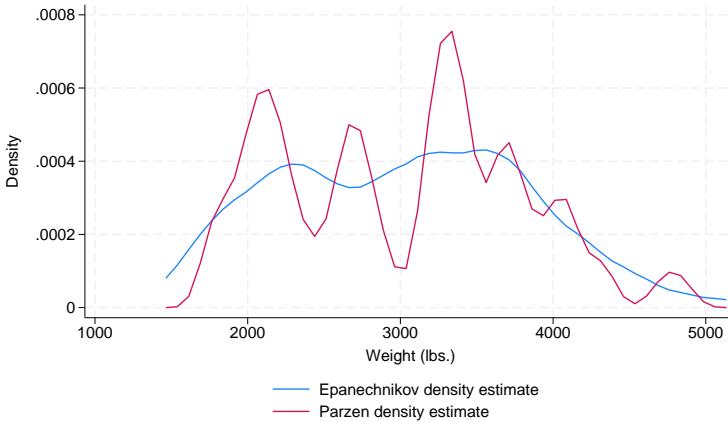

### ► Example 2: Different kernels can produce different results

When widths are held constant, different kernels can produce surprisingly different results. This is really an attribute of the kernel and width combination; for a given width, some kernels are more sensitive than others at identifying peaks in the density estimate.

We can see this when using a dataset with lots of peaks. In the automobile dataset, we characterize the density of `weight`, the weight of the vehicles. Below, we compare the Epanechnikov and Parzen kernels.

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. kdensity weight, kernel(epanechnikov) nograph generate(x epan)
. kdensity weight, kernel(parzen) nograph generate(x2 parzen)
. label var epan "Epanechnikov density estimate"
. label var parzen "Parzen density estimate"
. line epan parzen x, sort ytitle("Density") legend(pos(6))
```

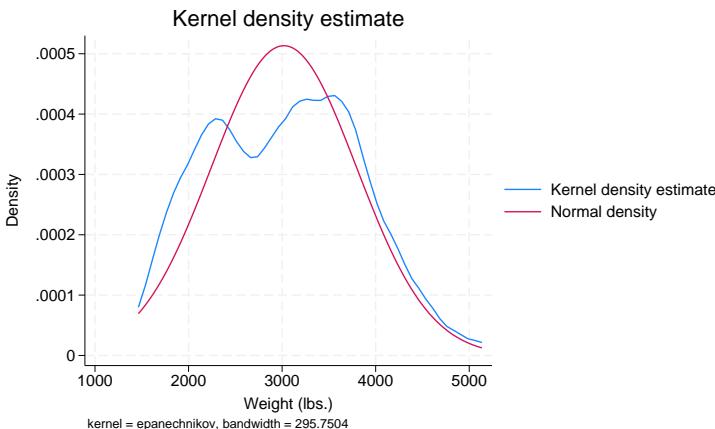

We did not specify a width, so we obtained the default width. That width is not a function of the selected kernel, but of the data. See [Methods and formulas](#) for the calculation of the optimal width.

▷ Example 3: Density with overlaid normal density

In examining the density estimates, we may wish to overlay a normal density or a Student's *t* density for comparison. Using automobile weights, we can get an idea of the distance from normality by using the normal option.

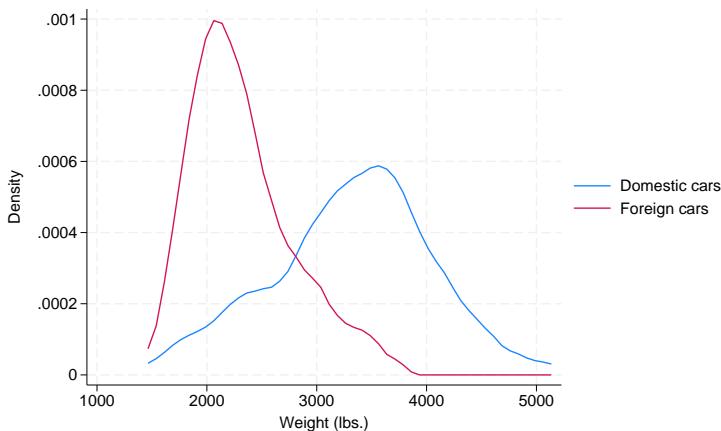

```
. kdensity weight, kernel(epanechnikov) normal
```

### ▷ Example 4: Compare two densities

We also may want to compare two or more densities. In this example, we will compare the density estimates of the weights for the foreign and domestic cars.

```
. use https://www.stata-press.com/data/r19/auto, clear
(1978 automobile data)
. kdensity weight, nograph generate(x fx)
. kdensity weight if foreign==0, nograph generate(fx0) at(x)
. kdensity weight if foreign==1, nograph generate(fx1) at(x)
. label var fx0 "Domestic cars"
. label var fx1 "Foreign cars"
. line fx0 fx1 x, sort ytitle(Density)
```

◀

### □ Technical note

Although all the examples we included had densities of less than 1, the density may exceed 1.

The probability density  $f(x)$  of a continuous variable,  $x$ , has the units and dimensions of the reciprocal of  $x$ . If  $x$  is measured in meters,  $f(x)$  has units 1/meter. Thus, the density is not measured on a probability scale, so it is possible for  $f(x)$  to exceed 1.

To see this, think of a uniform density on the interval 0 to 1. The area under the density curve is 1: this is the product of the density, which is constant at 1, and the range, which is 1. If the variable is then transformed by doubling, the area under the curve remains 1 and is the product of the density, constant at 0.5, and the range, which is 2. Conversely, if the variable is transformed by halving, the area under the curve also remains at 1 and is the product of the density, constant at 2, and the range, which is 0.5. (Strictly, the range is measured in certain units, and the density is measured in the reciprocal of those units, so the units cancel on multiplication.)

□

## Stored results

kdensity stores the following in `r()`:

Scalars

`r(bwidth)` kernel bandwidth  
`r(n)` number of points at which the estimate was evaluated  
`r(scale)` density bin width

Macros

`r(kernel)` name of kernel

## Methods and formulas

A kernel density estimate is formed by summing the weighted values calculated with the kernel function  $K$ , as in

$$\hat{f}_K = \frac{1}{qh} \sum_{i=1}^n w_i K\left(\frac{x - X_i}{h}\right)$$

where  $q = \sum_i w_i$  if weights are frequency weights (`fweight`) or analytic weights (`aweight`), and  $q = 1$  if weights are importance weights (`iweights`). Analytic weights are rescaled so that  $\sum_i w_i = n$  (see [\[U\] 11 Language syntax](#)). If weights are not used, then  $w_i = 1$ , for  $i = 1, \dots, n$ . `kdensity` includes seven different kernel functions. The Epanechnikov is the default function if no other kernel is specified and is the most efficient in minimizing the mean integrated squared error.

| Kernel       | Formula                                                                                                                                                          |  |

| Gaussian     | $K[z] = \frac{1}{\sqrt{2\pi}} e^{-z^2/2}$                                                                                                                        |  |
| Parzen       | $K[z] = \begin{cases} \frac{4}{3} - 8z^2 + 8 z ^3 & \text{if }  z  \leq 1/2 \\ 8(1 -  z )^3/3 & \text{if } 1/2 <  z  \leq 1 \\ 0 & \text{otherwise} \end{cases}$ |  |
| Rectangular  | $K[z] = \begin{cases} 1/2 & \text{if }  z  < 1 \\ 0 & \text{otherwise} \end{cases}$                                                                              |  |
| Triangular   | $K[z] = \begin{cases} 1 -  z  & \text{if }  z  < 1 \\ 0 & \text{otherwise} \end{cases}$                                                                          |  |

From the definitions given in the table, we can see that the choice of  $h$  will drive how many values are included in estimating the density at each point. This value is called the *window width* or *bandwidth*. If the window width is not specified, it is determined as

$$m = \min \left( \sqrt{\text{variance}_x}, \frac{\text{interquartile range}_x}{1.349} \right)$$

$$h = \frac{0.9m}{n^{1/5}}$$

where  $x$  is the variable for which we wish to estimate the kernel and  $n$  is the number of observations.

Most researchers agree that the choice of kernel is not as important as the choice of bandwidth. There is a great deal of literature on choosing bandwidths under various conditions; see, for example, [Parzen \(1962\)](#) or [Tapia and Thompson \(1978\)](#). Also see [Newton \(1988\)](#) for a comparison with sample spectral density estimation in time-series applications.

## Acknowledgments

We gratefully acknowledge the previous work by Isaías H. Salgado-Ugarte of the Universidad Nacional Autónoma de México, Makoto Shimizu of the University of Tokyo, and Toru Taniuchi formerly of the University of Tokyo; see [Salgado-Ugarte, Shimizu, and Taniuchi \(1993\)](#). Their article provides a good overview of the subject of univariate kernel density estimation and presents arguments for its use in exploratory data analysis.

[Description](#)[Options for two-sample test](#)[References](#)[Quick start](#)[Remarks and examples](#)[Also see](#)[Menu](#)[Stored results](#)[Syntax](#)[Methods and formulas](#)

## Description

`ksmirnov` performs one- and two-sample Kolmogorov–Smirnov tests of the equality of distributions. A one-sample test compares the distribution of the tested variable with the specified distribution. A two-sample test tests the equality of the distributions of two samples.

When testing for normality, please see [\[R\] sktest](#) and [\[R\] swilk](#).

## Quick start

One-sample test comparing the distribution of `v1` with a Student's  $t$  distribution with 5 degrees of freedom

```
ksmirnov v1 = t(5, v1)
```

Two-sample test comparing distributions of `v2` in two groups defined by `catvar`

```
ksmirnov v2, by(catvar)
```

Same as above, but calculate an exact  $p$ -value

```
ksmirnov v2, by(catvar) exact
```

## Menu

Statistics > Nonparametric analysis > Tests of hypotheses > Kolmogorov–Smirnov test

## Syntax

One-sample Kolmogorov–Smirnov test

```
ksmirnov varname = exp [if] [in]
```

Two-sample Kolmogorov–Smirnov test

```
ksmirnov varname [if] [in], by(groupvar) [exact]
```

In the first syntax, *varname* is the variable whose distribution is being tested, and *exp* must evaluate to the corresponding (theoretical) cumulative. In the second syntax, *groupvar* must take on two distinct values. The distribution of *varname* for the first value of *groupvar* is compared with that of the second value.

`collect` is allowed; see [U] 11.1.10 Prefix commands.

## Options for two-sample test

Main

`by(groupvar)` is required. It specifies a binary variable that identifies the two groups.

`exact` specifies that the exact *p*-value be computed.

## Remarks and examples

### ► Example 1: Two-sample test

Say that we have data on *x* that resulted from two different experiments, labeled as `group==1` and `group==2`. Our data contain

```
. use https://www.stata-press.com/data/r19/ksxmpl
. list
```

|    | group | x  |
|----|-------|----|
| 1. | 2     | 2  |
| 2. | 1     | 0  |
| 3. | 2     | 3  |
| 4. | 1     | 4  |
| 5. | 1     | 5  |
| 6. | 2     | 8  |
| 7. | 2     | 10 |

We wish to use the two-sample Kolmogorov–Smirnov test to determine if there are any differences in the distribution of  $x$  for these two groups:

```
. ksmirnov x, by(group)
Two-sample Kolmogorov-Smirnov test for equality of distribution functions
```

| Smaller group | D       | p-value |
|---------------|---------|---------|
| 1             | 0.5000  | 0.424   |
| 2             | -0.1667 | 0.909   |
| Combined K-S  | 0.5000  | 0.785   |

The first line tests the hypothesis that  $x$  for group 1 contains *smaller* values than for group 2. The largest difference between the distribution functions is 0.5. The approximate asymptotic  $p$ -value for this is 0.424, which is not significant.

The second line tests the hypothesis that  $x$  for group 1 contains *larger* values than for group 2. The largest difference between the distribution functions in this direction is 0.1667. The approximate asymptotic  $p$ -value for this small difference is 0.909.

Finally, the approximate asymptotic  $p$ -value for the combined test is 0.785. The approximate  $p$ -values `ksmirnov` calculates are based on the five-term approximation of the asymptotic distributions derived by [Smirnov \(1933\)](#). These approximations are not good for small samples ( $n < 50$ ). They are too conservative.

An exact  $p$ -value can be calculated using the exact option:

```
. ksmirnov x, by(group) exact
Two-sample Kolmogorov-Smirnov test for equality of distribution functions
```

| Smaller group | D       | p-value | Exact |
|---------------|---------|---------|-------|
| 1             | 0.5000  | 0.424   |       |
| 2             | -0.1667 | 0.909   |       |
| Combined K-S  | 0.5000  | 0.785   | 0.657 |

◀

## ► Example 2: One-sample test

Let's now test whether  $x$  in the example above is distributed normally. Kolmogorov–Smirnov is not a particularly powerful test in testing for normality, and we do not endorse such use of it; see [\[R\] sktest](#) and [\[R\] swilk](#) for better tests.

In any case, we will test against a normal distribution with the same mean and standard deviation:

```
. summarize x
```

| Variable | Obs | Mean     | Std. dev. | Min | Max |
|----------|-----|----------|-----------|-----|-----|
| x        | 7   | 4.571429 | 3.457222  | 0   | 10  |

```
. ksmirnov x = normal((x-4.571429)/3.457222)
One-sample Kolmogorov-Smirnov test against theoretical distribution
normal((x-4.571429)/3.457222)
```

| Smaller group | D       | p-value |
|---------------|---------|---------|
| x             | 0.1650  | 0.683   |
| Cumulative    | -0.1250 | 0.803   |
| Combined K-S  | 0.1650  | 0.991   |

Because Stata has no way of knowing that we based this calculation on the calculated mean and standard deviation of  $x$ , the  $p$ -values will be slightly conservative in addition to being approximations. Nevertheless, they clearly indicate that the data cannot be distinguished from normally distributed data. ◀

## Stored results

`ksmirnov` stores the following in `r()`:

### Scalars

|                         |                           |
|-------------------------|---------------------------|
| <code>r(D_1)</code>     | $D$ from line 1           |
| <code>r(p_1)</code>     | $p$ -value from line 1    |
| <code>r(D_2)</code>     | $D$ from line 2           |
| <code>r(p_2)</code>     | $p$ -value from line 2    |
| <code>r(D)</code>       | combined $D$              |
| <code>r(p)</code>       | combined $p$ -value       |
| <code>r(p_exact)</code> | exact combined $p$ -value |

### Macros

|                        |                           |
|------------------------|---------------------------|
| <code>r(group1)</code> | name of group from line 1 |
| <code>r(group2)</code> | name of group from line 2 |

## Methods and formulas

In general, the Kolmogorov–Smirnov test (Kolmogorov 1933; Smirnov 1933; also see Conover [1999], 428–465) is not very powerful against differences in the tails of distributions. In return for this, it is fairly powerful for alternative hypotheses that involve lumpiness or clustering in the data.

The directional hypotheses are evaluated with the statistics

$$D^+ = \max_x \{F(x) - G(x)\}$$

$$D^- = \min_x \{F(x) - G(x)\}$$

where  $F(x)$  and  $G(x)$  are the empirical distribution functions for the sample being compared. The combined statistic is

$$D = \max(|D^+|, |D^-|)$$

The  $p$ -value for this statistic may be obtained by evaluating the asymptotic limiting distribution. Let  $m$  be the sample size for the first sample, and let  $n$  be the sample size for the second sample. Smirnov (1933) shows that

$$\lim_{m,n \rightarrow \infty} \Pr \left\{ \sqrt{mn/(m+n)} D_{m,n} \leq z \right\} = 1 - 2 \sum_{i=1}^{\infty} (-1)^{i-1} \exp(-2i^2 z^2)$$

The first five terms form the approximation  $P_a$  used by Stata. The exact  $p$ -value is calculated by a counting algorithm; see Gibbons and Chakraborti (2011, 236–238).

Andrei Nikolayevich Kolmogorov (1903–1987), of Russia, was one of the great mathematicians of the twentieth century, making outstanding contributions in many different branches, including set theory, measure theory, probability and statistics, approximation theory, functional analysis, classical dynamics, and theory of turbulence. He was a faculty member at Moscow State University for more than 60 years.

Nikolai Vasilyevich Smirnov (1900–1966) was a Russian statistician whose work included contributions in nonparametric statistics, order statistics, and goodness of fit. After army service and the study of philosophy and philology, he turned to mathematics and eventually rose to be head of mathematical statistics at the Steklov Mathematical Institute in Moscow.

## Description

`kwallis` performs a Kruskal–Wallis test of the hypothesis that several samples are from the same population. This test is a multisample generalization of the two-sample Wilcoxon (Mann–Whitney) rank-sum test.

## Quick start

Test the equality of distribution of `v1` across all levels of categorical variable `cvar`

```
kwallis v1, by(cvar)
```

Same as above, but perform the test only for observations with `v2 = 1`

```
kwallis v1 if v2==1, by(cvar)
```

## Menu

Statistics > Nonparametric analysis > Tests of hypotheses > Kruskal–Wallis rank test

## Syntax

```
kwallis varname [if] [in], by(groupvar)
```

`collect` is allowed; see [U] [11.1.10 Prefix commands](#).

## Option

`by(groupvar)` is required. It specifies a variable that identifies the groups.

## Remarks and examples

### ▷ Example 1

We have data on the 50 states. The data contain the median age of the population, `medage`, and the region of the country, `region`, for each state. We wish to test for the equality of the median age distribution across all four regions simultaneously:

```
. use https://www.stata-press.com/data/r19/census
(1980 Census data by state)
. kwallis medage, by(region)
Kruskal-Wallis equality-of-populations rank test
```

| region  | Obs | Rank sum |
|---------|-----|----------|
| NE      | 9   | 376.50   |
| N Cntrl | 12  | 294.00   |
| South   | 16  | 398.00   |
| West    | 13  | 206.50   |

```
chi2(3) = 17.041
Prob = 0.0007
chi2(3) with ties = 17.062
Prob = 0.0007
```

From the output, we see that we can reject the hypothesis that the populations are the same at any level below 0.07%.

◀

## Stored results

kwallis stores the following in `r()`:

Scalars

```
r(df) degrees of freedom
r(chi2) χ^2
r(chi2_adj) χ^2 adjusted for ties
```

## Methods and formulas

The Kruskal–Wallis test (Kruskal and Wallis 1952, 1953; also see Altman [1991, 213–215]; Conover [1999, 288–297]; and Riffenburgh [2012, sec. 11.6]) is a multiple-sample generalization of the two-sample Wilcoxon (also called Mann–Whitney) rank-sum test (Wilcoxon 1945; Mann and Whitney 1947). Samples of sizes  $n_j$ ,  $j = 1, \dots, m$ , are combined and ranked in ascending order of magnitude. Tied values are assigned the average ranks. Let  $n$  denote the overall sample size, and let  $R_j = \sum_{i=1}^{n_j} R(X_{ji})$  denote the sum of the ranks for the  $j$ th sample. The Kruskal–Wallis one-way analysis-of-variance test,  $H$ , is defined as

$$H = \frac{1}{S^2} \left\{ \sum_{j=1}^m \frac{R_j^2}{n_j} - \frac{n(n+1)^2}{4} \right\}$$

where

$$S^2 = \frac{1}{n-1} \left\{ \sum_{\text{all ranks}} R(X_{ji})^2 - \frac{n(n+1)^2}{4} \right\}$$

If there are no ties, this equation simplifies to

$$H = \frac{12}{n(n+1)} \sum_{j=1}^m \frac{R_j^2}{n_j} - 3(n+1)$$

The sampling distribution of  $H$  is approximately  $\chi^2$  with  $m-1$  degrees of freedom.

William Henry Kruskal (1919–2005) was born in New York City. He studied mathematics and statistics at Antioch College, Harvard, and Columbia, and joined the University of Chicago in 1951. He made many outstanding contributions to linear models, nonparametric statistics, government statistics, and the history and methodology of statistics.

Wilson Allen Wallis (1912–1998) was born in Philadelphia. He studied psychology and economics at the Universities of Minnesota and Chicago and at Columbia. He taught at Yale, Stanford, and Chicago, before moving as president (later chancellor) to the University of Rochester in 1962. He also served in several Republican administrations. Wallis served as editor of the *Journal of the American Statistical Association*, coauthored a popular introduction to statistics, and contributed to nonparametric statistics.

## ladder — Ladder of powers

Description

Options for ladder

Stored results

Also see

Quick start

Options for gladder

Methods and formulas

Menu

Options for qladder

Acknowledgment

Syntax

Remarks and examples

References

## Description

`ladder` searches a subset of the ladder of powers (Tukey 1977) for a transform that converts *varname* into a normally distributed variable.

`gladder` and `qladder` each display a graph matrix. `gladder` displays nine histograms of transforms of *varname* according to the ladder of powers. `qladder` displays the quantiles of transforms of *varname* according to the ladder of powers against the quantiles of a normal distribution.

## Quick start

Table showing Tukey's ladder of powers transformations for *v*

```
ladder v
```

Same as above, but with separate tables for each level of the categorical variable *catvar*

```
by catvar: ladder v
```

Display transformations graphically using histograms

```
gladder v
```

Same as above, but using quantile plots

```
qladder v
```

## Menu

### ladder

Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder of powers

### gladder

Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder-of-powers histograms

### qladder

Statistics > Summaries, tables, and tests > Distributional plots and tests > Ladder-of-powers quantile-normal plots

## Syntax

*Ladder of powers*

```
ladder varname [if] [in] [, generate(newvar) noadjust]
```

*Ladder-of-powers histograms*

```
gladder varname [if] [in] [, histogram_options combine_options]
```

*Ladder-of-powers quantile–normal plots*

```
qladder varname [if] [in] [, qnorm_options combine_options]
```

by and collect are allowed with ladder; see [U] 11.1.10 Prefix commands.

## Options for ladder

Main

`generate(newvar)` saves the transformed values corresponding to the minimum  $\chi^2$  value from the table. We do not recommend using `generate()` because it is literal in interpreting the minimum, thus ignoring nearly equal but perhaps more interpretable transforms.

`noadjust` is the `noadjust` option to `sktest`; see [R] [sktest](#).

## Options for gladder

*histogram\_options* affect the rendition of the histograms across all relevant transformations; see [R] [histogram](#). Here the `normal` option is assumed, so you must supply the `nonnormal` option to suppress the overlaid normal density. Also, `gladder` does not allow the `width(#)` option of `histogram`.

*combine\_options* are any of the options documented in [G-2] [graph combine](#). These include options for titling the graph (see [G-3] [title\\_options](#)) and for saving the graph to disk (see [G-3] [saving\\_option](#)).

## Options for qladder

*qnorm\_options* affect the rendition of the quantile–normal plots across all relevant transformations. See [R] [Diagnostic plots](#).

*combine\_options* are any of the options documented in [G-2] [graph combine](#). These include options for titling the graph (see [G-3] [title\\_options](#)) and for saving the graph to disk (see [G-3] [saving\\_option](#)).

## Remarks and examples

### ▷ Example 1: ladder

We have data on the mileage rating of 74 automobiles and wish to find a transform that makes the variable normally distributed:

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
```

```
. ladder mpg
```

| Transformation  | Formula               | chi2(2) | Prob > chi2 |
|-----------------|-----------------------|---------|-------------|
| Cubic           | $\text{mpg}^3$        | 43.59   | 0.000       |
| Square          | $\text{mpg}^2$        | 27.03   | 0.000       |
| Identity        | $\text{mpg}$          | 10.95   | 0.004       |
| Square root     | $\sqrt{\text{mpg}}$   | 4.94    | 0.084       |
| Log             | $\log(\text{mpg})$    | 0.87    | 0.647       |
| 1/(Square root) | $1/\sqrt{\text{mpg}}$ | 0.20    | 0.905       |
| Inverse         | $1/\text{mpg}$        | 2.36    | 0.307       |
| 1/Square        | $1/(\text{mpg}^2)$    | 11.99   | 0.002       |
| 1/Cubic         | $1/(\text{mpg}^3)$    | 24.30   | 0.000       |

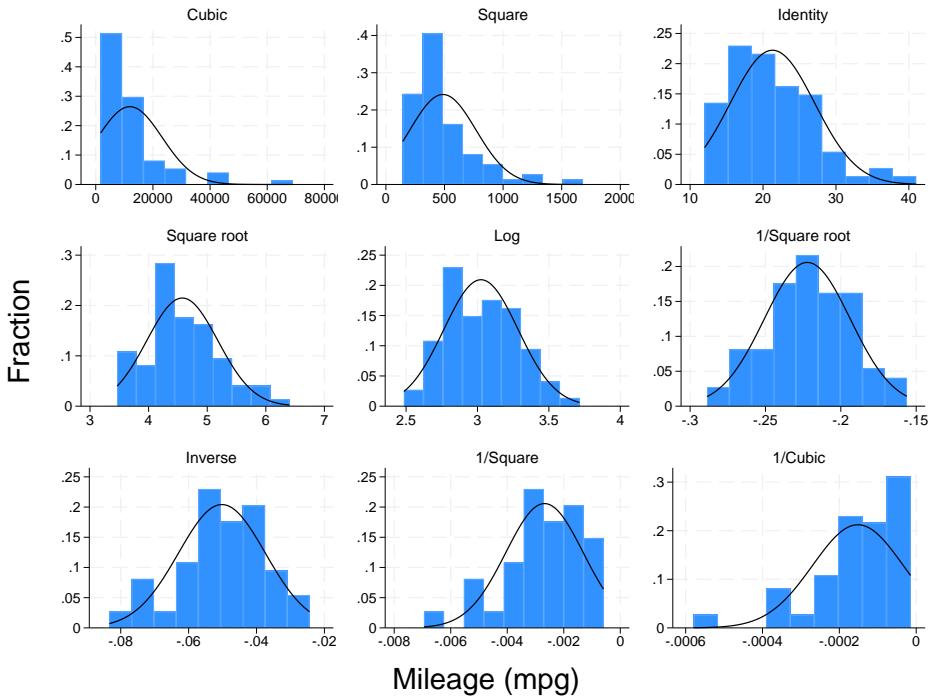

If we had typed `ladder mpg, gen(mpgx)`, the variable `mpgx` containing  $1/\sqrt{\text{mpg}}$  would have been automatically generated for us. This is the perfect example of why you should not, in general, specify the `generate()` option. We also cannot reject the hypothesis that the inverse of `mpg` is normally distributed and that  $1/\text{mpg}$ —gallons per mile—has a better interpretation. It is a measure of energy consumption.

◀

## ► Example 2: gladder

gladder explores the same transforms as ladder but presents results graphically:

```
. gladder mpg, fraction
```

Histograms by transformation

## □ Technical note

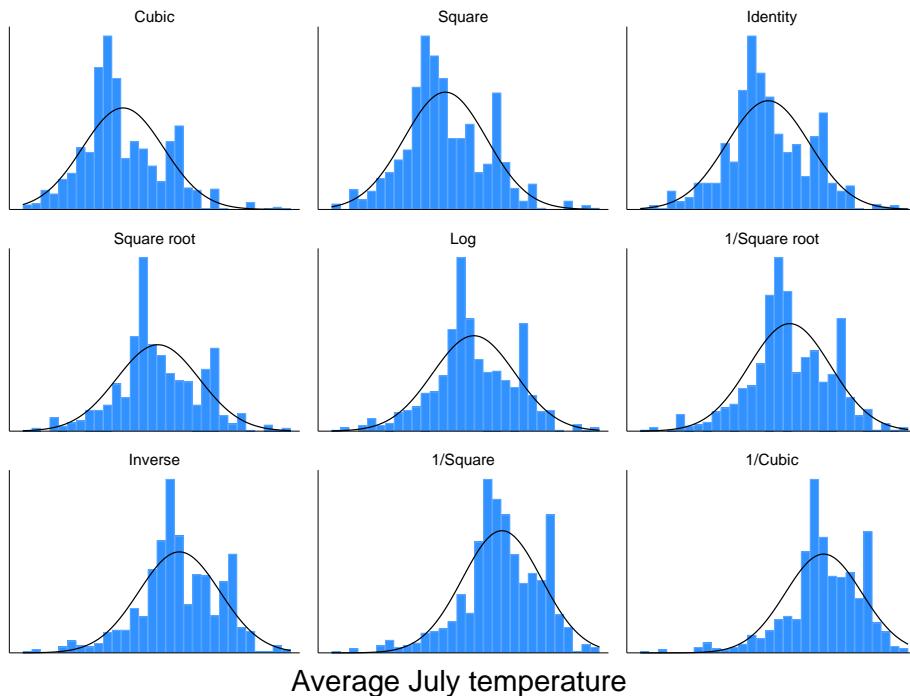

gladder is useful pedagogically, but be careful when using it for research work, especially with many observations. For instance, consider the following data on the average July temperature in degrees Fahrenheit for 954 US cities:

```
. use https://www.stata-press.com/data/r19/citytemp
(City temperature data)
. ladder tempjuly
```

| Transformation  | Formula                    | chi2(2) | Prob > chi2 |
|-----------------|----------------------------|---------|-------------|
| Cubic           | tempjuly <sup>3</sup>      | 47.49   | 0.000       |
| Square          | tempjuly <sup>2</sup>      | 19.70   | 0.000       |
| Identity        | tempjuly                   | 3.83    | 0.147       |
| Square root     | sqrt(tempjuly)             | 1.83    | 0.400       |
| Log             | log(tempjuly)              | 5.40    | 0.067       |
| 1/(Square root) | 1/sqrt(tempjuly)           | 13.72   | 0.001       |
| Inverse         | 1/tempjuly                 | 26.36   | 0.000       |
| 1/Square        | 1/(tempjuly <sup>2</sup> ) | 64.44   | 0.000       |
| 1/Cubic         | 1/(tempjuly <sup>3</sup> ) | 116.16  | 0.000       |

From the table, we see that there is certainly a difference in normality between the square and square-root transform. If, however, you can see the difference between the transforms in the diagram below, you have better eyes than we do:

```
. gladder tempjuly, l1title("") ylabel(none) xlabel(none)
```

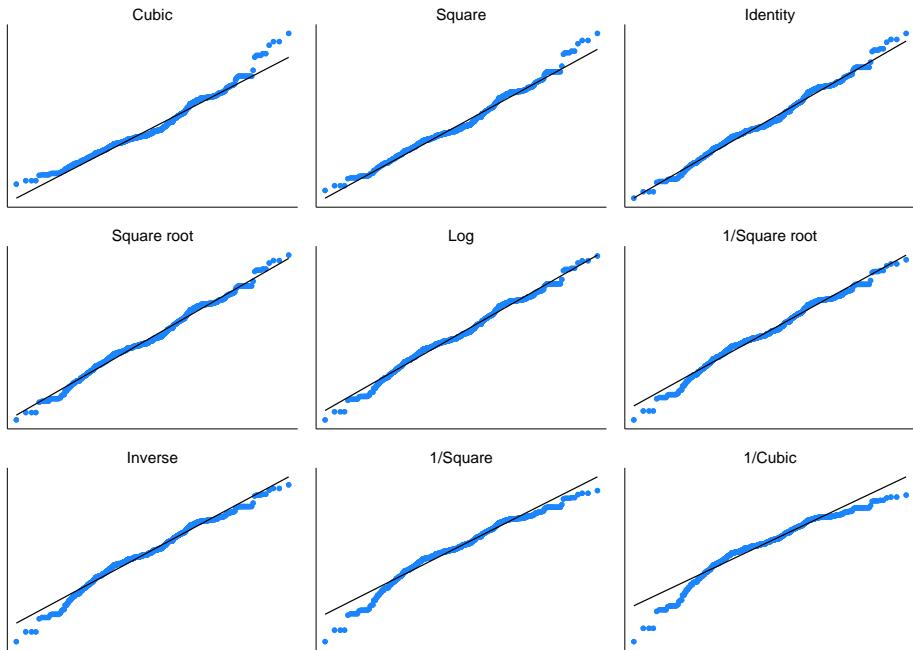

Histograms by transformation

### ▷ Example 3: qladder

A better graph for seeing normality is the quantile–normal graph, which can be produced by `qladder`.

```
. qladder tempjuly, ylabel(none) xlabel(none)
```

Average July temperature

Quantile–normal plots by transformation

This graph shows that for the square transform, the upper tail—and only the upper tail—diverges from what would be expected. This divergence is detected by `sktest` (see [R] [sktest](#)) as a problem with skewness, as we would learn from using `sktest` to examine `tempjuly squared` and `tempjuly sqrt`.

## Stored results

`ladder` stores the following in `r()`:

Scalars

|                           |                                                                   |
|---------------------------|-------------------------------------------------------------------|
| <code>r(N)</code>         | number of observations                                            |
| <code>r(invcube)</code>   | $\chi^2$ for inverse-cubic transformation                         |
| <code>r(P_invcube)</code> | $p$ -value for normality test after inverse-cubic transformation  |
| <code>r(invsq)</code>     | $\chi^2$ for inverse-square transformation                        |
| <code>r(P_invsq)</code>   | $p$ -value for normality test after inverse-square transformation |
| <code>r(inv)</code>       | $\chi^2$ for inverse transformation                               |
| <code>r(P_inv)</code>     | $p$ -value for normality test after inverse transformation        |
| <code>r(invsqrt)</code>   | $\chi^2$ for inverse-root transformation                          |
| <code>r(P_invsqrt)</code> | $p$ -value for normality test after inverse-root transformation   |
| <code>r(log)</code>       | $\chi^2$ for log transformation                                   |
| <code>r(P_log)</code>     | $p$ -value for normality test after log transformation            |
| <code>r(sqrt)</code>      | $\chi^2$ for square-root transformation                           |
| <code>r(P_sqrt)</code>    | $p$ -value for normality test after square-root transformation    |
| <code>r(ident)</code>     | $\chi^2$ for untransformed data                                   |
| <code>r(P_ident)</code>   | $p$ -value for normality test of untransformed data               |
| <code>r(square)</code>    | $\chi^2$ for square transformation                                |
| <code>r(P_square)</code>  | $p$ -value for normality test after square transformation         |
| <code>r(cube)</code>      | $\chi^2$ for cubic transformation                                 |
| <code>r(P_cube)</code>    | $p$ -value for normality test after cubic transformation          |

## Methods and formulas

For `ladder`, results are as reported by `sktest`; see [\[R\] sktest](#). If `generate()` is specified, the transform with the minimum  $\chi^2$  value is chosen.

`gladder` sets the number of bins to  $\min(\sqrt{n}, 10 \log_{10} n)$ , rounded to the closest integer, where  $n$  is the number of unique values of `varname`. See [\[R\] histogram](#) for a discussion of the optimal number of bins.

Also see [Findley \(1990\)](#) for a ladder-of-powers variable transformation program that produces one-way graphs with overlaid box plots, in addition to histograms with overlaid normals. [Buchner and Findley \(1990\)](#) discuss ladder-of-powers transformations as one aspect of preliminary data analysis. Also see [Hamilton \(1992, 18–23\)](#) and [Hamilton \(2013, 129–132\)](#).

## Acknowledgment

`qladder` was written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

## Description

`set level` specifies the default confidence level for confidence intervals for all commands that report confidence intervals. The initial value is 95, meaning 95% confidence intervals.

## Syntax

```
set level # [, permanently]
```

# is any number between 10.00 and 99.99 and may be specified with at most two digits after the decimal point.

## Option

`permanently` specifies that, in addition to making the change right now, the `level` setting be remembered and become the default setting when you invoke Stata.

## Remarks and examples

To change the level of confidence intervals reported by a particular command, you need not reset the default confidence level. All commands that report confidence intervals have a `level(#)` option. When you do not specify the option, the confidence intervals are calculated for the default level set by `set level`, or for 95% if you have not reset `set level`.

### ▷ Example 1

We use the `ci means` command to obtain the confidence interval for the mean of `mpg`:

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. ci means mpg
```

| Variable | Obs | Mean    | Std. err. | [95% conf. interval] |          |
|----------|-----|---------|-----------|----------------------|----------|
| mpg      | 74  | 21.2973 | .6725511  | 19.9569              | 22.63769 |

To obtain 90% confidence intervals, we would type

```
. ci means mpg, level(90)
```

| Variable | Obs | Mean    | Std. err. | [90% conf. interval] |          |
|----------|-----|---------|-----------|----------------------|----------|
| mpg      | 74  | 21.2973 | .6725511  | 20.17683             | 22.41776 |

or

```
. set level 90
. ci means mpg
```

| Variable | Obs | Mean    | Std. err. | [90% conf. interval] |          |
|----------|-----|---------|-----------|----------------------|----------|
| mpg      | 74  | 21.2973 | .6725511  | 20.17683             | 22.41776 |

If we opt for the second alternative, the next time that we fit a model (say, with `regress`), 90% confidence intervals will be reported. If we wanted 95% confidence intervals, we could specify `level(95)` on the estimation command, or we could reset the default by typing `set level 95`.

The current setting of `level()` is stored as the c-class value `c(level)`; see [P] [creturn](#).

## Description

This entry provides a quick reference for the size limits in Stata. Note that most of these limits are so high that you will never encounter them.

## Remarks and examples

Remarks are presented under the following headings:

*Maximum size limits*  
*Determining which edition of Stata you are running*

### Maximum size limits

- (1) For Stata/MP, the maximum number of observations is 1,099,511,627,775, and for Stata/SE, the maximum number is 2,147,483,619. In practice, both editions are limited by memory.
- (2) The maximum length of the contents of a macro are fixed in Stata/BE and settable in Stata/SE and Stata/MP. The currently set maximum length is recorded in `c(macrolen)`; type `display c(macrolen)`. The maximum length can be changed with `set maxvar`. If you set `maxvar` to a larger value, the maximum length increases; if you set `maxvar` to a smaller value, the maximum length decreases. The relationship between them is  $maximum\_length = 129 \times maxvar + 200$ .
- (3) In Mata, matrices are limited only by the amount of memory on your computer.

## Determining which edition of Stata you are running

Type

```
. about
```

The response will be Stata/MP, Stata/SE, or Stata/BE. Other information is also shown, including your serial number. See [R] [about](#).

## Description

`lincom` computes point estimates, standard errors,  $t$  or  $z$  statistics,  $p$ -values, and confidence intervals for linear combinations of parameters after any estimation command, including survey estimation. Results can optionally be displayed as odds ratios, hazard ratios, incidence-rate ratios, or relative-risk ratios.

## Quick start

Point estimate and confidence interval for sum of coefficients of `x1` and `x2`

```
lincom x1 + x2
```

Same as above, but report results as a relative-risk ratio

```
lincom x1 + x2, rrr
```

Same as above, but use coefficients from second equation of a multiequation model

```
lincom [2]x1 + [2]x2, rrr
```

Difference between coefficients of first and third level of categorical variable `a`

```
lincom 1.a - 3.a
```

Sum of coefficients of `x1` and `x2` after a model adjusted for complex survey design

```
lincom x1 + x2
```

## Menu

Statistics > Postestimation

## Syntax

```
lincom exp [, options]
```

| <i>options</i>               | Description                                                                                       |
|------------------------------|---------------------------------------------------------------------------------------------------|
| <code>eform</code>           | generic label; $\exp(b)$                                                                          |
| <code>or</code>              | odds ratio                                                                                        |
| <code>hr</code>              | hazard ratio                                                                                      |
| <code>shr</code>             | subhazard ratio                                                                                   |
| <code>irr</code>             | incidence-rate ratio                                                                              |
| <code>rrr</code>             | relative-risk ratio                                                                               |
| <code>level(#)</code>        | set confidence level; default is <code>level(95)</code>                                           |
| <code>display_options</code> | control column formats                                                                            |
| <code>df(#)</code>           | use $t$ distribution with # degrees of freedom for computing $p$ -values and confidence intervals |

*exp* is any linear combination of parameters that is a valid syntax for `test`; see [R] `test`. *exp* must not contain an equal sign.

`collect` is allowed; see [U] 11.1.10 **Prefix commands**.

`df(#)` does not appear in the dialog box.

## Options

`eform`, `or`, `hr`, `shr`, `irr`, and `rrr` all report coefficient estimates as  $\exp(\hat{\beta})$  rather than  $\hat{\beta}$ . Standard errors and confidence intervals are similarly transformed. `or` is the default after `logistic`. The only difference in these options is how the output is labeled.

| Option             | Label                   | Explanation          | Example commands             |
|--------------------|-------------------------|----------------------|------------------------------|
| <code>eform</code> | <code>exp(b)</code>     | Generic label        | <code>cloglog</code>         |
| <code>or</code>    | <code>Odds ratio</code> | Odds ratio           | <code>logistic, logit</code> |
| <code>hr</code>    | <code>Haz. ratio</code> | Hazard ratio         | <code>stcox, streg</code>    |
| <code>shr</code>   | <code>SHR</code>        | Subhazard ratio      | <code>stcrreg</code>         |
| <code>irr</code>   | <code>IRR</code>        | Incidence-rate ratio | <code>poisson</code>         |
| <code>rrr</code>   | <code>RRR</code>        | Relative-risk ratio  | <code>mlogit</code>          |

*exp* may not contain any additive constants when you use the `eform`, `or`, `hr`, `irr`, or `rrr` option.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 **Specifying the width of confidence intervals**.

`display_options`: `cformat(%fmt)`, `pformat(%fmt)`, and `sformat(%fmt)`; see [R] **Estimation options**.

The following option is available with `lincom` but is not shown in the dialog box:

`df(#)` specifies that the  $t$  distribution with # degrees of freedom be used for computing  $p$ -values and confidence intervals. The default is to use `e(df_r)` degrees of freedom or the standard normal distribution if `e(df_r)` is missing.

## Remarks and examples

Remarks are presented under the following headings:

*Using lincom*  
*Odds ratios and incidence-rate ratios*  
*Multiple-equation models*

### Using lincom

After fitting a model and obtaining estimates for coefficients  $\beta_1, \beta_2, \dots, \beta_k$ , you may want to view estimates for linear combinations of the  $\beta_i$ , such as  $\beta_1 - \beta_2$ . `lincom` can display estimates for any linear combination of the form  $c_0 + c_1\beta_1 + c_2\beta_2 + \dots + c_k\beta_k$ .

`lincom` works after any estimation command for which `test` works. Any valid expression for `test` syntax 1 (see [R] `test`) is a valid expression for `lincom`.

`lincom` is useful for viewing odds ratios, hazard ratios, etc., for one group (that is, one set of covariates) relative to another group (that is, another set of covariates). See the examples below.

#### ► Example 1

We perform a linear regression:

```
. use https://www.stata-press.com/data/r19/regress
. regress y x1 x2 x3
```

| Source   | SS         | df  | MS         | Number of obs | = | 148    |
|----------|------------|-----|------------|---------------|---|--------|
| Model    | 3259.3561  | 3   | 1086.45203 | F(3, 144)     | = | 96.12  |
| Residual | 1627.56282 | 144 | 11.3025196 | Prob > F      | = | 0.0000 |
|          |            |     |            | R-squared     | = | 0.6670 |
|          |            |     |            | Adj R-squared | = | 0.6600 |
| Total    | 4886.91892 | 147 | 33.2443464 | Root MSE      | = | 3.3619 |

| y     | Coefficient | Std. err. | t      | P> t  | [95% conf. interval] |           |
|-------|-------------|-----------|--------|-------|----------------------|-----------|
| x1    | 1.457113    | 1.07461   | 1.36   | 0.177 | -.666934             | 3.581161  |
| x2    | 2.221682    | .8610358  | 2.58   | 0.011 | .5197797             | 3.923583  |
| x3    | -.006139    | .0005543  | -11.08 | 0.000 | -.0072345            | -.0050435 |
| _cons | 36.10135    | 4.382693  | 8.24   | 0.000 | 27.43863             | 44.76407  |

To see the difference of the coefficients of `x2` and `x1`, we type

```
. lincom x2 - x1
(1) - x1 + x2 = 0
```

| y   | Coefficient | Std. err. | t    | P> t  | [95% conf. interval] |          |
|-----|-------------|-----------|------|-------|----------------------|----------|
| (1) | .7645682    | .9950282  | 0.77 | 0.444 | -1.20218             | 2.731316 |

The expression can be any linear combination.

```
. lincom 3*x1 + 500*x3
(1) 3*x1 + 500*x3 = 0
```

| y   | Coefficient | Std. err. | t    | P> t  | [95% conf. interval] |          |
|-----|-------------|-----------|------|-------|----------------------|----------|
| (1) | 1.301825    | 3.396624  | 0.38 | 0.702 | -5.411858            | 8.015507 |

Nonlinear expressions are not allowed.

```
. lincom x2/x1
not possible with test
r(131);
```

For information about estimating nonlinear expressions, see [R] [nlcom](#).

### □ Technical note

`lincom` uses the same shorthands for coefficients as does `test` (see [R] [test](#)). When you type `x1`, for instance, `lincom` knows that you mean the coefficient of `x1`. The formal syntax for referencing this coefficient is actually `_b[x1]`, or alternatively, `_coef[x1]`. So, more formally, in the last example we could have typed

```
. lincom 3*_b[x1] + 500*_b[x3]
```

## Odds ratios and incidence-rate ratios

After logistic regression, the `or` option can be specified with `lincom` to display odds ratios for any effect. Incidence-rate ratios after commands such as `poisson` can be similarly obtained by specifying the `irr` option.

### ▷ Example 2

Consider the low birthweight dataset from [Hosmer, Lemeshow, and Sturdivant \(2013, 24\)](#). We fit a logistic regression model of low birthweight (variable `low`) on the following variables:

| Variable                | Description                                                              | Coding                             |
|-------------------------|--------------------------------------------------------------------------|------------------------------------|
| <code>age</code>        | age in years                                                             |                                    |
| <code>race</code>       | race                                                                     | 1 if white, 2 if black, 3 if other |
| <code>smoke</code>      | smoking status                                                           | 1 if smoker, 0 if nonsmoker        |
| <code>ht</code>         | history of hypertension                                                  | 1 if yes, 0 if no                  |
| <code>ui</code>         | uterine irritability                                                     | 1 if yes, 0 if no                  |
| <code>lwd</code>        | maternal weight before pregnancy                                         | 1 if weight < 110 lb., 0 otherwise |
| <code>ptd</code>        | history of premature labor                                               | 1 if yes, 0 if no                  |
| <code>c.age##lwd</code> | age main effects, <code>lwd</code> main effects, and their interaction   |                                    |
| <code>smoke##lwd</code> | smoke main effects, <code>lwd</code> main effects, and their interaction |                                    |

We first fit a model without the interaction terms by using logit.

```
. use https://www.stata-press.com/data/r19/lbw3
(Hosmer & Lemeshow data)
. logit low age lwd i.race smoke ptd ht ui
Iteration 0: Log likelihood = -117.336
Iteration 1: Log likelihood = -99.3982
Iteration 2: Log likelihood = -98.780418
Iteration 3: Log likelihood = -98.777998
Iteration 4: Log likelihood = -98.777998
Logistic regression
Number of obs = 189
LR chi2(8) = 37.12
Prob > chi2 = 0.0000
Pseudo R2 = 0.1582
Log likelihood = -98.777998
```

| low   | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|-------------|-----------|-------|-------|----------------------|----------|
| age   | -.0464796   | .0373888  | -1.24 | 0.214 | -.1197603            | .0268011 |
| lwd   | .8420615    | .4055338  | 2.08  | 0.038 | .0472299             | 1.636893 |
| race  |             |           |       |       |                      |          |
| Black | 1.073456    | .5150753  | 2.08  | 0.037 | .0639273             | 2.082985 |
| Other | .815367     | .4452979  | 1.83  | 0.067 | -.0574008            | 1.688135 |
| smoke | .8071996    | .404446   | 2.00  | 0.046 | .0145001             | 1.599899 |
| ptd   | 1.281678    | .4621157  | 2.77  | 0.006 | .3759478             | 2.187408 |
| ht    | 1.435227    | .6482699  | 2.21  | 0.027 | .1646414             | 2.705813 |
| ui    | .6576256    | .4666192  | 1.41  | 0.159 | -.2569313            | 1.572182 |
| _cons | -1.216781   | .9556797  | -1.27 | 0.203 | -3.089878            | .656317  |

To get the odds ratio for black smokers relative to white nonsmokers (the reference group), we type

```
. lincom 2.race + smoke, or
(1) [low]2.race + [low]smoke = 0
```

| low | Odds ratio | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|------------|-----------|------|-------|----------------------|----------|
| (1) | 6.557805   | 4.744692  | 2.60 | 0.009 | 1.588176             | 27.07811 |

lincom computed  $\exp(\beta_{2.race} + \beta_{smoke}) = 6.56$ . To see the odds ratio for white smokers relative to black nonsmokers, we type

```
. lincom smoke - 2.race, or
(1) - [low]2.race + [low]smoke = 0
```

| low | Odds ratio | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-----|------------|-----------|-------|-------|----------------------|----------|
| (1) | .7662425   | .4430176  | -0.46 | 0.645 | .2467334             | 2.379603 |

Now let's add the interaction terms to the model (Hosmer and Lemeshow 1989, table 4.10). This time, we will use logistic rather than logit. By default, logistic displays odds ratios.

```
. logistic low i.race ht ui ptd c.age##lwd smoke##lwd
Logistic regression Number of obs = 189
 LR chi2(10) = 42.66
 Prob > chi2 = 0.0000
Log likelihood = -96.00616 Pseudo R2 = 0.1818
```

| _cons     |            |           |       |       |                      |          |
|           | .599443    | .6519163  | -0.47 | 0.638 | .0711271             | 5.051971 |

Note: **\_cons** estimates baseline odds.

Hosmer and Lemeshow (1989, table 4.13) consider the effects of smoking (smoke = 1) and low maternal weight before pregnancy (lwd = 1). The effect of smoking among non-low-weight mothers (lwd = 0) is given by the odds ratio 3.17 for smoke in the logistic output. The effect of smoking among low-weight mothers is given by

```
. lincom 1.smoke + 1.smoke#1.lwd
(1) [low]1.smoke + [low]1.smoke#1.lwd = 0
```

| low | Odds ratio | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-----|------------|-----------|-------|-------|----------------------|----------|
| (1) | .7755022   | .574951   | -0.34 | 0.732 | .1813465             | 3.316323 |

We did not have to specify the or option. After logistic, lincom assumes or by default.

The effect of low weight (lwd = 1) is more complicated because we fit an age × lwd interaction. We must specify the age of mothers for the effect. The effect among 30-year-old nonsmokers is given by

```
. lincom 1.lwd + 30*1.lwd#c.age
(1) [low]1.lwd + 30*[low]1.lwd#c.age = 0
```

| low | Odds ratio | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|------------|-----------|------|-------|----------------------|----------|
| (1) | 14.7669    | 13.5669   | 2.93 | 0.003 | 2.439264             | 89.39633 |

lincom computed  $\exp(\beta_{1wd} + 30\beta_{age1wd}) = 14.8$ . It may seem odd that we entered it as `1.1wd + 30*1.1wd#c.age`, but remember that these terms are just lincom's (and test's) shorthands for `_b[1.1wd]` and `_b[1.1wd#c.age]`. We could have typed

```
. lincom _b[1.1wd] + 30*_b[1.1wd#c.age]
(1) [low]1.1wd + 30*[low]1.1wd#c.age = 0
```

|     | low | Odds ratio | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|-----|------------|-----------|------|-------|----------------------|----------|
| (1) |     | 14.7669    | 13.5669   | 2.93 | 0.003 | 2.439264             | 89.39633 |

## Multiple-equation models

lincom also works with multiple-equation models. The only difference is how you refer to the coefficients. Recall that for multiple-equation models, coefficients are referenced using the syntax

`[eqno]varname`

where *eqno* is the equation number or equation name and *varname* is the corresponding variable name for the coefficient; see [\[U\] 13.5 Accessing coefficients and standard errors](#) and [\[R\] test](#) for details.

### ▷ Example 3

Let's consider [example 4](#) from [\[R\] mlogit](#) (Tarlov et al. 1989; Wells et al. 1989).

```
. use https://www.stata-press.com/data/r19/sysdsn1
(Health insurance data)
. mlogit insure age male nonwhite i.site, nolog
(output omitted)
```

To see the estimate of the sum of the coefficient of `male` and the coefficient of `nonwhite` for the `Prepaid` outcome, we type

```
. lincom [Prepaid]male + [Prepaid]nonwhite
(1) [Prepaid]male + [Prepaid]nonwhite = 0
```

|     | insure | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|--------|-------------|-----------|------|-------|----------------------|----------|
| (1) |        | 1.53647     | .3272489  | 4.70 | 0.000 | .8950741             | 2.177866 |

To view the estimate as a ratio of relative risks (see [\[R\] mlogit](#) for the definition and interpretation), we specify the `rrr` option.

```
. lincom [Prepaid]male + [Prepaid]nonwhite, rrr
(1) [Prepaid]male + [Prepaid]nonwhite = 0
```

|     | insure | RRR      | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-----|--------|----------|-----------|------|-------|----------------------|----------|
| (1) |        | 4.648154 | 1.521103  | 4.70 | 0.000 | 2.447517             | 8.827451 |

## Stored results

lincom stores the following in `r()`:

Scalars

|                                        |                                    |
|----------------------------------------|------------------------------------|
| <code>r(estimate)</code>               | point estimate                     |
| <code>r(se)</code>                     | estimate of standard error         |
| <code>r(df)</code>                     | degrees of freedom                 |
| <code>r(t)</code> or <code>r(z)</code> | $t$ or $z$ statistic               |
| <code>r(p)</code>                      | $p$ -value                         |
| <code>r(lb)</code>                     | lower bound of confidence interval |
| <code>r(ub)</code>                     | upper bound of confidence interval |
| <code>r(level)</code>                  | confidence level                   |

## Description

`linktest` performs a link test for model specification.

## Quick start

Specification link test after a single-equation estimation command without options

```
linktest
```

After `tobit` estimated with right-censoring limit at 24

```
linktest, ul(24)
```

After `stcox` estimated with Efron method for tied failures

```
linktest, efron
```

Perform test on full dataset when estimation used a subset of observations

```
linktest if e(sample) < .
```

## Menu

Statistics > Postestimation

## Syntax

```
linktest [if] [in] [, cmd_options]
```

When `if` and `in` are not specified, the link test is performed on the same sample as the previous estimation.

`collect` is allowed; see [U] [11.1.10 Prefix commands](#).

## Option

Main

*cmd\_options* must be the same options specified with the underlying estimation command, except the *display\_options* may differ.

## Remarks and examples

The form of the link test implemented here is based on an idea of [Tukey \(1949\)](#), which was further described by [Pregibon \(1980\)](#), elaborating on work in his unpublished thesis ([Pregibon 1979](#)). See *Methods and formulas* below for more details.

### ▷ Example 1

We want to explain the mileage ratings of cars in our automobile dataset by using the weight, engine displacement, and whether the car is manufactured outside the United States:

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. regress mpg weight displ foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 1619.71935 | 3  | 539.906448 | F(3, 70)      | = | 45.88  |
| Residual | 823.740114 | 70 | 11.7677159 | Prob > F      | = | 0.0000 |
|          |            |    |            | R-squared     | = | 0.6629 |
|          |            |    |            | Adj R-squared | = | 0.6484 |
| Total    | 2443.45946 | 73 | 33.4720474 | Root MSE      | = | 3.4304 |

| mpg          | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |           |
|--------------|-------------|-----------|-------|-------|----------------------|-----------|
| weight       | -.0067745   | .0011665  | -5.81 | 0.000 | -.0091011            | -.0044479 |
| displacement | .0019286    | .0100701  | 0.19  | 0.849 | -.0181556            | .0220129  |
| foreign      | -1.600631   | 1.113648  | -1.44 | 0.155 | -3.821732            | .6204699  |
| _cons        | 41.84795    | 2.350704  | 17.80 | 0.000 | 37.15962             | 46.53628  |

On the basis of the  $R^2$ , we are reasonably pleased with this model.

If our model really is specified correctly, then if we were to regress mpg on the prediction and the prediction squared, the prediction squared would have no explanatory power. This is what `linktest` does:

```
. linktest
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 1670.71514 | 2  | 835.357572 | F(2, 71)      | = | 76.75  |
| Residual | 772.744316 | 71 | 10.8837228 | Prob > F      | = | 0.0000 |
|          |            |    |            | R-squared     | = | 0.6837 |
|          |            |    |            | Adj R-squared | = | 0.6748 |
| Total    | 2443.45946 | 73 | 33.4720474 | Root MSE      | = | 3.299  |

| mpg    | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|--------|-------------|-----------|-------|-------|----------------------|----------|
| _hat   | -.4127198   | .6577736  | -0.63 | 0.532 | -1.724283            | .8988434 |
| _hatsq | .0338198    | .015624   | 2.16  | 0.034 | .0026664             | .0649732 |
| _cons  | 14.00705    | 6.713276  | 2.09  | 0.041 | .6211539             | 27.39294 |

We find that the prediction squared does have explanatory power, so our specification is not as good as we thought.

Although linktest is formally a test of the specification of the dependent variable, it is often interpreted as a test that, conditional on the specification, the independent variables are specified incorrectly. We will follow that interpretation and now include weight squared in our model:

```
. regress mpg weight c.weight#c.weight displ foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 1699.02634 | 4  | 424.756584 | F(4, 69)      | = | 39.37  |
| Residual | 744.433124 | 69 | 10.7888859 | Prob > F      | = | 0.0000 |
|          |            |    |            | R-squared     | = | 0.6953 |
|          |            |    |            | Adj R-squared | = | 0.6777 |
| Total    | 2443.45946 | 73 | 33.4720474 | Root MSE      | = | 3.2846 |

| mpg                   | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |           |
|-----------------------|-------------|-----------|-------|-------|----------------------|-----------|
| weight                | -.0173257   | .0040488  | -4.28 | 0.000 | -.0254028            | -.0092486 |
| c.weight#<br>c.weight | 1.87e-06    | 6.89e-07  | 2.71  | 0.008 | 4.93e-07             | 3.24e-06  |
| displacement          | -.0101625   | .0106236  | -0.96 | 0.342 | -.031356             | .011031   |
| foreign               | -2.560016   | 1.123506  | -2.28 | 0.026 | -4.801349            | -.3186832 |
| _cons                 | 58.23575    | 6.449882  | 9.03  | 0.000 | 45.36859             | 71.10291  |

Now, we perform the link test on our new model:

```
. linktest
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | 1699.39489 | 2  | 849.697445 | F(2, 71)      | = | 81.08  |
| Residual | 744.06457  | 71 | 10.4797827 | Prob > F      | = | 0.0000 |
|          |            |    |            | R-squared     | = | 0.6955 |
|          |            |    |            | Adj R-squared | = | 0.6869 |
| Total    | 2443.45946 | 73 | 33.4720474 | Root MSE      | = | 3.2372 |

| mpg    | Coefficient | Std. err. | t     | P> t  | [95% conf. interval] |          |
|--------|-------------|-----------|-------|-------|----------------------|----------|
| _hat   | 1.141987    | .7612218  | 1.50  | 0.138 | -.3758456            | 2.659821 |
| _hatsq | -.0031916   | .0170194  | -0.19 | 0.852 | -.0371272            | .0307441 |
| _cons  | -1.50305    | 8.196444  | -0.18 | 0.855 | -17.84629            | 14.84019 |

We now pass the link test.

## ▷ Example 2

Above, we followed a standard misinterpretation of the link test—when we discovered a problem, we focused on the explanatory variables of our model. We might consider varying exactly what the link test tests. The link test told us that our dependent variable was misspecified. For those with an engineering background, mpg is indeed a strange measure. It would make more sense to model energy consumption—gallons per mile—in terms of weight and displacement:

```
. gen gpm = 1/mpg
. regress gpm weight displ foreign
```

| Source   | SS         | df | MS         | Number of obs | = | 74     |
|----------|------------|----|------------|---------------|---|--------|
| Model    | .009157962 | 3  | .003052654 | F(3, 70)      | = | 76.33  |
| Residual | .002799666 | 70 | .000039995 | Prob > F      | = | 0.0000 |
|          |            |    |            | R-squared     | = | 0.7659 |
|          |            |    |            | Adj R-squared | = | 0.7558 |
| Total    | .011957628 | 73 | .000163803 | Root MSE      | = | .00632 |

| gpm          | Coefficient | Std. err. | t    | P> t  | [95% conf. interval] |          |
|--------------|-------------|-----------|------|-------|----------------------|----------|
| weight       | .0000144    | 2.15e-06  | 6.72 | 0.000 | .0000102             | .0000187 |
| displacement | .0000186    | .0000186  | 1.00 | 0.319 | -.0000184            | .0000557 |
| foreign      | .0066981    | .0020531  | 3.26 | 0.002 | .0026034             | .0107928 |
| _cons        | .0008917    | .0043337  | 0.21 | 0.838 | -.0077515            | .009535  |

This model looks every bit as reasonable as our original model:

```
. linktest
```

Specifying the model in terms of gallons per mile also solves the specification problem and results in a more parsimonious specification.

## ▷ Example 3

The link test can be used with any single-equation estimation procedure, not solely regression. Let's turn our problem around and attempt to explain whether a car is manufactured outside the United States by its mileage rating and weight. To save paper, we will specify `logit`'s `nolog` option, which suppresses the iteration log:

```
. logit foreign mpg weight, nolog
Logistic regression Number of obs = 74
 LR chi2(2) = 35.72
 Prob > chi2 = 0.0000
Log likelihood = -27.175156 Pseudo R2 = 0.3966
```

| foreign | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|---------|-------------|-----------|-------|-------|----------------------|----------|
| mpg     | -.1685869   | .0919175  | -1.83 | 0.067 | -.3487418            | .011568  |
| weight  | -.0039067   | .0010116  | -3.86 | 0.000 | -.0058894            | -.001924 |
| _cons   | 13.70837    | 4.518709  | 3.03  | 0.002 | 4.851859             | 22.56487 |

When we run `linktest` after `logit`, the result is another logit specification:

```
. linktest, nolog
Logistic regression Number of obs = 74
 LR chi2(2) = 36.83
 Prob > chi2 = 0.0000
Log likelihood = -26.615714 Pseudo R2 = 0.4090
```

| foreign | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|---------|-------------|-----------|-------|-------|----------------------|----------|
| _hat    | .8438531    | .2738759  | 3.08  | 0.002 | .3070661             | 1.38064  |
| _hatsq  | -.1559115   | .1568642  | -0.99 | 0.320 | -.4633596            | .1515366 |
| _cons   | .2630557    | .4299598  | 0.61  | 0.541 | -.57965              | 1.105761 |

The link test reveals no problems with our specification.

If there had been a problem, we would have been virtually forced to accept the misinterpretation of the link test—we would have reconsidered our specification of the independent variables. When using `logit`, we have no control over the specification of the dependent variable other than to change likelihood functions.

We admit to having seen a dataset once for which the link test rejected the logit specification. We did change the likelihood function, refitting the model using `probit`, and satisfied the link test. `Probit` has thinner tails than `logit`. In general, however, you will not be so lucky.

## □ Technical note

You should specify the same options with `linktest` that you do with the estimation command, although you do not have to follow this advice as literally as we did in the preceding example. `logit`'s `nolog` option merely suppresses a part of the output, not what is estimated. We specified `nolog` both times to save space.

If you are testing a tobit model, you must specify the censoring points just as you do with the `tobit` command.

If you are not sure which options are important, duplicate exactly what you specified on the estimation command.

If you do not specify `if exp` or `in range` with `linktest`, Stata will by default perform the link test on the same sample as the previous estimation. Suppose that you omitted some data when performing your estimation but want to calculate the link test on all the data, which you might do if you believe the model is appropriate for all the data. You would type `linktest if e(sample) < .` to do this.

□

## Stored results

`linktest` stores the following in `r()`:

Scalars

|                    |                                           |
|--------------------|-------------------------------------------|
| <code>r(t)</code>  | <i>t</i> statistic on <code>_hatsq</code> |
| <code>r(df)</code> | degrees of freedom                        |

`linktest` is *not* an estimation command in the sense that it leaves previous estimation results unchanged. For instance, after running a regression and performing the link test, typing `regress` without arguments after the link test still replays the original regression.

For integrating an estimation command with `linktest`, `linktest` assumes that the name of the estimation command is stored in `e(cmd)` and that the name of the dependent variable is stored in `e(depvar)`. After estimation, it assumes that the number of degrees of freedom for the *t* test is given by `e(df_m)` if the macro is defined.

If the estimation command reports *z* statistics instead of *t* statistics, `linktest` will also report *z* statistics. The *z* statistic, however, is still returned in `r(t)`, and `r(df)` is set to a missing value.

## Methods and formulas

The link test is based on the idea that if a regression or regression-like equation is properly specified, you should be able to find no additional independent variables that are significant except by chance. One kind of specification error is called a link error. In regression, this means that the dependent variable needs a transformation or “link” function to properly relate to the independent variables. The idea of a link test is to add an independent variable to the equation that is especially likely to be significant if there is a link error.

Let

$$\mathbf{y} = f(\mathbf{X}\boldsymbol{\beta})$$

be the model and  $\widehat{\boldsymbol{\beta}}$  be the parameter estimates. `linktest` calculates

$$\_hat = \mathbf{X}\widehat{\boldsymbol{\beta}}$$

and

$$\_hatsq = \_hat^2$$

The model is then refit with these two variables, and the test is based on the significance of `_hatsq`. This is the form suggested by Pregibon (1979) based on an idea of Tukey (1949). Pregibon (1980) suggests a slightly different method that has come to be known as “Pregibon’s goodness-of-link test”. We prefer the older version because it is universally applicable, straightforward, and a good second-order approximation. It can be applied to any single-equation estimation technique, whereas Pregibon’s more recent tests are estimation-technique specific.

## Description

`lnskew0` creates  $newvar = \ln(\pm exp - k)$ , choosing  $k$  and the sign of  $exp$  so that the skewness of  $newvar$  is zero.

`bcskew0` creates  $newvar = (exp^\lambda - 1)/\lambda$ , the Box–Cox power transformation (Box and Cox 1964), choosing  $\lambda$  so that the skewness of  $newvar$  is zero.  $exp$  must be strictly positive.

## Quick start

Generate `newv1`, the zero-skewness log transform of continuous variable `v1`

```
lnskew0 newv1 = v1
```

Same as above, but transform ratio of `v1` to `v2`

```
lnskew0 newv1 = v1/v2
```

Zero-skewness Box–Cox transform, `newv2`, of `v2`

```
bcskew0 newv2 = v2
```

Same as above, and change the value for convergence to 0.0001 from the default 0.001

```
bcskew0 newv2 = v2, zero(.0001)
```

## Menu

Description

Main

| <i>options</i>   | Description                                                                                                   |
|------------------|---------------------------------------------------------------------------------------------------------------|
| <u>d</u> elta(#) | increment for derivative of skewness function; default is delta(0.02) for lnskew0 and delta(0.01) for bcskew0 |
| <u>z</u> ero(#)  | value for determining convergence; default is zero(0.001)                                                     |
| <u>l</u> evel(#) | compute the confidence interval at confidence level #; by default, no confidence interval is calculated       |

collect is allowed with lnskew0 and bcskew0; see [\[U\] 11.1.10 Prefix commands](#).

## Options

Main

`delta(#)` specifies the increment used for calculating the derivative of the skewness function with respect to  $k$  (lnskew0) or  $\lambda$  (bcskew0). The default values are 0.02 for lnskew0 and 0.01 for bcskew0.

`zero(#)` specifies a value for skewness to determine convergence that is small enough to be considered zero and is, by default, 0.001.

`level(#)` specifies the confidence level for the confidence interval for  $k$  (lnskew0) or  $\lambda$  (bcskew0). The confidence interval is calculated only if `level()` is specified. # is specified as an integer; 95 means 95% confidence intervals. The `level()` option is honored only if the number of observations exceeds 7.

## Remarks and examples

### ▷ Example 1: Inskew0

Using our automobile dataset (see [U] 1.2.2 Example datasets), we want to generate a new variable equal to  $\ln(\text{mpg} - k)$  to be approximately normally distributed. `mpg` records the miles per gallon for each of our cars. One feature of the normal distribution is that it has skewness 0.

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. lnskew0 lnmpg = mpg
```

| Transform           | k        | [95% conf. interval] | Skewness  |
|---------------------|----------|----------------------|-----------|
| $\ln(\text{mpg}-k)$ | 5.383659 | (not calculated)     | -7.05e-06 |

This created the new variable `lnmpg = ln(mpg - 5.384)`:

```
. describe lnmpg
```

| Variable name      | Storage type | Display format | Value label | Variable label                |
|--------------------|--------------|----------------|-------------|-------------------------------|
| <code>lnmpg</code> | float        | %9.0g          |             | <code>ln(mpg-5.383659)</code> |

Because we did not specify the `level()` option, no confidence interval was calculated. At the outset, we could have typed

```
. use https://www.stata-press.com/data/r19/auto, clear
(1978 automobile data)
. lnskew0 lnmpg = mpg, level(95)
```

| Transform           | k        | [95% conf. interval] | Skewness  |
|---------------------|----------|----------------------|-----------|
| $\ln(\text{mpg}-k)$ | 5.383659 | -17.12339 9.892416   | -7.05e-06 |

The confidence interval is calculated under the assumption that  $\ln(\text{mpg} - k)$  really does have a normal distribution. It would be perfectly reasonable to use `lnskew0`, even if we did not believe that the transformed variable would have a normal distribution—if we literally wanted the zero-skewness transform—although, then the confidence interval would be an approximation of unknown quality to the true confidence interval. If we now wanted to test the believability of the confidence interval, we could also test our new variable `lnmpg` by using `swilk` (see [R] [swilk](#)) with the `lnnormal` option.

□ Technical note

lnskew0 and bcskew0 report the resulting skewness of the variable merely to reassure you of the accuracy of its results. In our example above, lnskew0 found  $k$  such that the resulting skewness was  $-7 \times 10^{-6}$ , a number close enough to zero for all practical purposes. If we wanted to make it even smaller, we could specify the zero() option. Typing lnskew0 new=mpg, zero(1e-8) changes the estimated  $k$  to 5.383552 from 5.383659 and reduces the calculated skewness to  $-2 \times 10^{-11}$ .

When you request a confidence interval, lnskew0 may report the lower confidence interval as ‘.’, which should be taken as indicating the lower confidence limit  $k_L = -\infty$ . (This cannot happen with bcskew0.)

As an example, consider a sample of size  $n$  on  $x$  and assume that the skewness of  $x$  is positive, but not significantly so, at the desired significance level—say, 5%. Then, no matter how large and negative you make  $k_L$ , there is no value extreme enough to make the skewness of  $\ln(x - k_L)$  equal the corresponding percentile (97.5 for a 95% confidence interval) of the distribution of skewness in a normal distribution of the same sample size. You cannot do this because the distribution of  $\ln(x - k_L)$  tends to that of  $x$ —apart from location and scale shift—as  $x \rightarrow \infty$ . This “problem” never applies to the upper confidence limit,  $k_U$ , because the skewness of  $\ln(x - k_U)$  tends to  $-\infty$  as  $k$  tends upward to the minimum value of  $x$ . □

▷ Example 2: bcskew0

In example 1, using lnskew0 with a variable such as mpg is probably undesirable. mpg has a natural zero, and we are shifting that zero arbitrarily. On the other hand, use of lnskew0 with a variable such as temperature measured in Fahrenheit or Celsius would be more appropriate because the zero is indeed arbitrary.

For a variable like mpg, it makes more sense to use the Box–Cox power transform (Box and Cox 1964):

$$y^{(\lambda)} = \frac{y^\lambda - 1}{\lambda}$$

$\lambda$  is free to take on any value, but  $y^{(1)} = y - 1$ ,  $y^{(0)} = \ln(y)$ , and  $y^{(-1)} = 1 - 1/y$ .

bcskew0 works like lnskew0:

```
. bcskew0 bcmpg = mpg, level(95)
```

| Transform   | L         | [95% conf. interval] |          |  | Skewness |
|-------------|-----------|----------------------|----------|--|----------|
| (mpg^L-1)/L | -.3673283 | -1.212752            | .4339645 |  | .0001898 |

The 95% confidence interval includes  $\lambda = -1$  ( $\lambda$  is labeled L in the output), which has a rather more pleasing interpretation—gallons per mile—than  $(\text{mpg}^{-0.3673} - 1)/(-0.3673)$ . The confidence interval, however, is calculated assuming that the power transformed variable is normally distributed. It makes perfect sense to use bcskew0, even when you do not believe that the transformed variable will be normally distributed, but then the confidence interval is an approximation of unknown quality. If you believe that the transformed data are normally distributed, you can alternatively use boxcox to estimate  $\lambda$ ; see [R] boxcox.

## Stored results

lnskew0 and bcskew0 store the following in `r()`:

Scalars

|                          |                                            |
|--------------------------|--------------------------------------------|
| <code>r(gamma)</code>    | $k$ (lnskew0)                              |
| <code>r(lambda)</code>   | $\lambda$ (bcskew0)                        |
| <code>r(lb)</code>       | lower bound of confidence interval         |
| <code>r(ub)</code>       | upper bound of confidence interval         |
| <code>r(skewness)</code> | resulting skewness of transformed variable |

## Methods and formulas

Skewness is as calculated by `summarize`; see [R] [summarize](#). Newton's method with numeric, uncentered derivatives is used to estimate  $k$  (lnskew0) and  $\lambda$  (bcskew0). For lnskew0, the initial value is chosen so that the minimum of  $x - k$  is 1, and thus  $\ln(x - k)$  is 0. bcskew0 starts with  $\lambda = 1$ .

## Acknowledgment

lnskew0 and bcskew0 were written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

## Description

`log` and its subcommands tell Stata to open a log file and create a record of what you type and any output that appears in the Results window, to suspend or resume logging, to check logging status, and to close the log file. The default format is Stata Markup and Control Language (SMCL) but can be plain text. You can have up to five SMCL and five text logs open at a time. `cmdlog` and its subcommands are similar to `log` but create a command log recording only what you type and can be only plain text. That is, `cmdlog` is designed only for interactive use. You can have only one command log open at a time.

`set logtype`, `set logmsg`, and `set linesize` are commands to control system parameters that relate to logs.

## Quick start

Begin recording your Stata session in `mylog.smcl`

```
log using mylog
```

Same as above, but use a text format that can be read by a word processor

```
log using mylog, text
```

Save a subset of output to `mylog2.smcl` while `mylog.smcl` is still open

```
log using mylog2, name(mylog2)
```

Close `mylog2.smcl` and keep `mylog.smcl` open

```
log close mylog2
```

Create a do-file from commands typed interactively

```
cmdlog using mydo.do
```

## Menu

File > Log

## Syntax

*Report status of log file*

```
log
```

```
log query [logname | _all]
```

*Open log file*

```
log using filename [, append replace [text | smc1] name(logname) [nomsg | msg]]
```

*Close log*

```
log close [logname | _all]
```

*Temporarily suspend logging or resume logging*

```
log { off | on } [logname]
```

*Report status of command log file*

```
cmdlog
```

*Open command log file*

```
cmdlog using filename [, append replace]
```

*Close command log, temporarily suspend logging, or resume logging*

```
cmdlog { close | on | off }
```

*Set default format for logs*

```
set logtype { text | smc1 } [, permanently]
```

*Set default for display of log messages*

```
set logmsg { on | off }
```

*Specify screen width*

```
set linesize #
```

In addition to using the log command, you may access the capabilities of log by selecting **File > Log** from the menu and choosing one of the options in the list.

collect is allowed with log query, log, and cmdlog; see [U] [11.1.10 Prefix commands](#).

## Options for use with both log and cmdlog

`append` specifies that results be appended to an existing file. If the file does not already exist, a new file is created.

`replace` specifies that *filename*, if it already exists, be overwritten. When you do not specify either `replace` or `append`, the file is assumed to be new. If the specified file already exists, an error message is issued and logging is not started.

## Options for use with log

`text` and `smcl` specify the format in which the log is to be recorded. The default is complicated to describe but is what you would expect:

If you specify the file as *filename*.`smcl`, the default is to write the log in SMCL format (regardless of the value of `set logtype`).

If you specify the file as *filename*.`log`, the default is to write the log in text format (regardless of the value of `set logtype`).

If you type *filename* without an extension and specify neither the `smcl` option nor the `text` option, the default is to write the file according to the value of `set logtype`. If you have not `set logtype`, then the default is SMCL. Also, the *filename* you specified will be fixed to read *filename*.`smcl` if a SMCL log is being created or *filename*.`log` if a text log is being created.

If you specify either the `text` or `smcl` option, then what you specify determines how the log is written. If *filename* was specified without an extension, the appropriate extension is added for you.

If you open multiple log files, you may choose a different format for each file.

`name(logname)` specifies an optional name you may use to refer to the log while it is open. You can start multiple log files, give each a different *logname*, and then close, temporarily suspend, or resume them each individually. The default *logname* is `<unnamed>`.

`nomsg` and `msg` specify whether to display or suppress the default message at the top and bottom of the log file.

`nomsg` suppresses the default message displayed at the top and bottom of the log file. This message consists of the log name (if specified in `name()`, otherwise `unnamed`), log path, log type, and date opened or closed.

`msg` displays the default message at the top and bottom of the log file. This option is for use when `set logmsg` is turned off.

## Option for use with set logtype

`permanently` specifies that, in addition to making the change right now, the `logtype` setting be remembered and become the default setting when you invoke Stata.

## Remarks and examples

A full log is a file containing what you type and Stata's output that is shown in the Results window. To begin logging your session, you type `log` using *filename*. If *filename* contains embedded spaces, remember to enclose it in double quotation marks.

When the default log format is SMCL, `log` will add the extension `.smcl` if *filename* is specified without one. If *text* is specified or the default log type is changed to `text`, `log` adds the extension `.log`.

We recommend using SMCL because it preserves fonts and colors. SMCL logs can be viewed and printed from the Viewer window, as can any text file; see [R] [view](#). Users of console Stata can use `translate` to produce printable versions of log files. `translate` also converts SMCL logs to text or other formats, such as PostScript or PDF; see [R] [translate](#).

When you open a full log, the default is to show the name of the file and a time and date stamp:

```
. log using myfile

 name: <unnamed>
 log: C:\data\proj1\myfile.smcl
 log type: smcl
opened on: 12 Jan 2025, 12:28:23
.
```

The above information will appear in the log. If you do not want this information to appear, precede the command by `quietly`:

```
. quietly log using myfile
```

`quietly` will not suppress any error messages or anything else you need to know.

Similarly, when you close a full log, the default is to show the full information,

```
. log close
 name: <unnamed>
 log: C:\data\proj1\myfile.smcl
 log type: smcl
closed on: 12 Jan 2025, 12:32:41

```

and that information will also appear in the log. If you want to suppress that, type `quietly log close`. Alternatively, specifying `nomsg` with `log using` will suppress these messages.

If you do not specify name (*logname*), Stata will use the name `<unnamed>`, as shown above. However, you can start multiple log files by specifying the `name()` option with each new `log using` command. To control a specific log, type, for example, `log close logname`; to close all log files at one time, type `log close _all`.

Stata also lets you log only your commands using `cmdlog`. Command logs are always text files, which makes them easy to convert to do-files. The default extension is `.txt` instead of `.do` to keep you from accidentally overwriting your important do-files. However, `cmdlog` will allow you to specify `.do` as the extension of *filename*.

You can have only one command log open at a time. However, you can have full logs open while logging your commands. Moreover, the text file you create for your command log does not count against the limit of five text logs.

`set logtype` specifies the default format in which full logs are to be recorded. Initially, full logs are recorded in SMCL format.

`set logmsg` specifies whether the default message is displayed at the top and bottom of the log file. The default is `on`. Specifying `set logmsg off` suppresses the default message from both `log using` and `log close` just as if the `nomsg` option were used with `log using`.

`set linesize` specifies the maximum width, in characters, of Stata output. Most commands in Stata do not respect `linesize`, because it is not important for most commands. Most users never need to set `linesize`, because it will automatically be reset if you resize your Results window. This is also why there is no permanently option allowed with `set linesize`. `set linesize` is for use with commands such as `list` and `display` and is typically used by programmers who wish the output of those commands to be wider or narrower than the current width of the Results window.

## Stored results

`log` and `cmdlog` store the following in `r()`:

Macros

|                          |                |
|--------------------------|----------------|
| <code>r(name)</code>     | <i>logname</i> |
| <code>r(filename)</code> | name of file   |
| <code>r(status)</code>   | on or off      |
| <code>r(type)</code>     | smcl or text   |

`log query _all` stores the following in `r()`:

Scalars

|                         |                          |
|-------------------------|--------------------------|
| <code>r(numlogs)</code> | number of open log files |
|-------------------------|--------------------------|

For each open log file, `log query _all` also stores

|                           |                |
|---------------------------|----------------|
| <code>r(name#)</code>     | <i>logname</i> |
| <code>r(filename#)</code> | name of file   |
| <code>r(status#)</code>   | on or off      |
| <code>r(type#)</code>     | smcl or text   |

where `#` varies between 1 and the value of `r(numlogs)`. Be aware that `#` will not necessarily represent the order in which the log files were first opened, nor will it necessarily remain constant for a given log file upon multiple calls to `log query`.

## Description

`logistic` fits a logistic regression model of *depvar* on *indepvars*, where *depvar* is a 0/1 variable (or, more precisely, a 0/non-0 variable). Without arguments, `logistic` redisplay the last `logistic` estimates. `logistic` displays estimates as odds ratios; to view coefficients, type `logit` after running `logistic`. To obtain odds ratios for any covariate pattern relative to another, see [R] [lincom](#).

## Quick start

Report odds ratios from logistic regression of *y* on *x1* and *x2*

```
logistic y x1 x2
```

Add indicators for values of categorical variable *a*

```
logistic y x1 x2 i.a
```

Same as above, and apply frequency weights defined by *wvar*

```
logistic y x1 x2 i.a [fweight=wvar]
```

Show base level of *a*

```
logistic y x1 x2 i.a, baselevels
```

## Menu

Statistics > Binary outcomes > Logistic regression

## Syntax

```
logistic devar indepvars [if] [in] [weight] [, options]
```

| <code>coeflegend</code>                      | display legend instead of statistics                                                                                                                                        |

*indepvars* may contain factor variables; see [U] 11.4.3 **Factor variables**.

*devar* and *indepvars* may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: logistic**.

`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] **mi estimate**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] **svy**.

`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 **weight**.

`collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options

Model

`noconstant`, `offset(varname)`, `constraints(constraints)`; see [R] **Estimation options**.

`asis` forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] **probit**.

## SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

## Reporting

`level(#)`; see [R] [Estimation options](#).

`coef` causes `logistic` to report the estimated coefficients rather than the odds ratios (exponentiated coefficients). `coef` may be specified when the model is fit or may be used later to redisplay results. `coef` affects only how results are displayed and not how they are estimated.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

## Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

The following options are available with `logistic` but are not shown in the dialog box:

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

[logistic and logit](#)  
[Robust estimate of variance](#)  
[Video examples](#)

## logistic and logit

`logistic` provides an alternative and preferred way to fit maximum-likelihood logit models, the other choice being `logit` ([R] [logit](#)).

First, let's dispose of some confusing terminology. We use the words `logit` and `logistic` to mean the same thing: maximum likelihood estimation. To some, one or the other of these words connotes transforming the dependent variable and using weighted least squares to fit the model, but that is not how we use either word here. Thus, the `logit` and `logistic` commands produce the same results.

The `logistic` command is generally preferred to the `logit` command because `logistic` presents the estimates in terms of odds ratios rather than coefficients. To some people, this may seem disadvantageous, but you can type `logit` without arguments after `logistic` to see the underlying coefficients. You should be cautious when interpreting the odds ratio of the constant term. Usually, this odds ratio represents the baseline odds of the model when all predictor variables are set to zero. However, you must verify that a zero value for all predictor variables in the model actually makes sense before continuing with this interpretation.

Nevertheless, `[R] logit` is still worth reading because `logistic` shares the same features as `logit`, including omitting variables due to collinearity or one-way causation.

For an introduction to logistic regression, see [Lemeshow and Hosmer \(2005\)](#), [Pagano and Gauvreau \(2022, 455–478\)](#), or [Pampel \(2021\)](#); for a complete but nonmathematical treatment, see [Kleinbaum and Klein \(2010\)](#); and for a thorough discussion, see [Hosmer, Lemeshow, and Sturdivant \(2013\)](#). See [Gould \(2000\)](#) for a discussion of the interpretation of logistic regression. See [Dupont \(2009\)](#) or [Hilbe \(2009\)](#) for a discussion of logistic regression with examples using Stata. For a discussion using Stata with an emphasis on model specification, see [Vittinghoff et al. \(2012\)](#).

Stata has a variety of commands for performing estimation when the dependent variable is dichotomous or polytomous. See [Long and Freese \(2014\)](#) for a book devoted to fitting these models with Stata. See `help estimation commands` for a complete list of all of Stata’s estimation commands.

## ▷ Example 1

Consider the following dataset from a study of risk factors associated with low birthweight described in [Hosmer, Lemeshow, and Sturdivant \(2013, 24\)](#).

```
. use https://www.stata-press.com/data/r19/lbw
(Hosmer & Lemeshow data)

. describe

Contains data from https://www.stata-press.com/data/r19/lbw.dta
Observations: 189 Hosmer & Lemeshow data
Variables: 11 15 Jan 2024 05:01
```

| Variable name | Storage type | Display format | Value label | Variable label                                     |
|---------------|--------------|----------------|-------------|----------------------------------------------------|
| id            | int          | %8.0g          |             | Identification code                                |

| ht            | byte         | %8.0g          |             | Has history of hypertension                        |
| ui            | byte         | %8.0g          |             | Presence, uterine irritability                     |
| ftv           | byte         | %8.0g          |             | Number of visits to physician during 1st trimester |
| bwt           | int          | %8.0g          |             | Birthweight (grams)                                |

Sorted by:

We want to investigate the causes of low birthweight. Here `race` is a categorical variable indicating whether a person is white (`race = 1`), black (`race = 2`), or some other race (`race = 3`). We want indicator (dummy) variables for `race` included in the regression, so we will use factor variables.

```
. logistic low age lwt i.race smoke ptl ht ui
Logistic regression
Log likelihood = -100.724
Number of obs = 189
LR chi2(8) = 33.22
Prob > chi2 = 0.0001
Pseudo R2 = 0.1416
```

| _cons | 1.586014   | 1.910496  | 0.38  | 0.702 | .1496092             | 16.8134  |

Note: `_cons` estimates baseline odds.

The odds ratios are for a one-unit change in the variable. If we wanted the odds ratio for age to be in terms of 4-year intervals, we would type

```
. generate age4 = age/4
. logistic low age4 lwt i.race smoke ptl ht ui
(output omitted)
```

After `logistic`, we can type `logit` to see the model in terms of coefficients and standard errors:

```
. logit
Logistic regression
Log likelihood = -100.724
Number of obs = 189
LR chi2(8) = 33.22
Prob > chi2 = 0.0001
Pseudo R2 = 0.1416
```

| low   | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |           |
|-------|-------------|-----------|-------|-------|----------------------|-----------|
| age4  | -.1084012   | .1458017  | -0.74 | 0.457 | -.3941673            | .1773649  |
| lwt   | -.0151508   | .0069259  | -2.19 | 0.029 | -.0287253            | -.0015763 |
| race  |             |           |       |       |                      |           |
| Black | 1.262647    | .5264101  | 2.40  | 0.016 | .2309024             | 2.294392  |
| Other | .8620792    | .4391532  | 1.96  | 0.050 | .0013548             | 1.722804  |
| smoke | .9233448    | .4008266  | 2.30  | 0.021 | .137739              | 1.708951  |
| ptl   | .5418366    | .346249   | 1.56  | 0.118 | -.136799             | 1.220472  |
| ht    | 1.832518    | .6916292  | 2.65  | 0.008 | .4769494             | 3.188086  |
| ui    | .7585135    | .4593768  | 1.65  | 0.099 | -.1418484            | 1.658875  |
| _cons | .4612239    | 1.20459   | 0.38  | 0.702 | -1.899729            | 2.822176  |

If we wanted to see the logistic output again, we would type `logistic` without arguments.

## ▶ Example 2

We can specify the confidence interval for the odds ratios with the `level()` option, and we can do this either at estimation time or when replaying the model. For instance, to see our first model in [example 1](#) with narrower, 90% confidence intervals, we might type

```
. logistic, level(90)
Logistic regression Number of obs = 189
 LR chi2(8) = 33.22
 Prob > chi2 = 0.0001
Log likelihood = -100.724 Pseudo R2 = 0.1416
```

| low   | Odds ratio | Std. err. | z     | P> z  | [90% conf. interval] |          |
|-------|------------|-----------|-------|-------|----------------------|----------|
| age4  | .8972675   | .1308231  | -0.74 | 0.457 | .7059409             | 1.140448 |
| lwt   | .9849634   | .0068217  | -2.19 | 0.029 | .9738063             | .9962483 |
| race  |            |           |       |       |                      |          |
| Black | 3.534767   | 1.860737  | 2.40  | 0.016 | 1.487028             | 8.402379 |
| Other | 2.368079   | 1.039949  | 1.96  | 0.050 | 1.149971             | 4.876471 |
| smoke |            |           |       |       |                      |          |
| ptl   | 2.517698   | 1.00916   | 2.30  | 0.021 | 1.302185             | 4.867819 |
| ht    | 1.719161   | .5952579  | 1.56  | 0.118 | .9726876             | 3.038505 |
| ui    | 6.249602   | 4.322408  | 2.65  | 0.008 | 2.003487             | 19.49478 |
| _cons | 2.1351     | .9808153  | 1.65  | 0.099 | 1.00291              | 4.545424 |
|       | 1.586014   | 1.910496  | 0.38  | 0.702 | .2186791             | 11.50288 |

Note: `_cons` estimates baseline odds.

◀

**Robust estimate of variance**

If you specify `vce(robust)`, Stata reports the robust estimate of variance described in [\[U\] 20.22 Obtaining robust variance estimates](#). Here is the model previously fit with the robust estimate of variance:

```
. logistic low age lwt i.race smoke ptl ht ui, vce(robust)
Logistic regression Number of obs = 189
 Wald chi2(8) = 29.02
 Prob > chi2 = 0.0003
Log pseudolikelihood = -100.724 Pseudo R2 = 0.1416
```

| low   | Odds ratio | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|------------|---------------------|-------|-------|----------------------|----------|
| age   | .9732636   | .0329376            | -0.80 | 0.423 | .9108015             | 1.040009 |
| lwt   | .9849634   | .0070209            | -2.13 | 0.034 | .9712984             | .9988206 |
| race  |            |                     |       |       |                      |          |
| Black | 3.534767   | 1.793616            | 2.49  | 0.013 | 1.307504             | 9.556051 |
| Other | 2.368079   | 1.026563            | 1.99  | 0.047 | 1.012512             | 5.538501 |
| smoke |            |                     |       |       |                      |          |
| ptl   | 2.517698   | .9736417            | 2.39  | 0.017 | 1.179852             | 5.372537 |
| ht    | 1.719161   | .7072902            | 1.32  | 0.188 | .7675715             | 3.850476 |
| ui    | 6.249602   | 4.102026            | 2.79  | 0.005 | 1.726445             | 22.6231  |
| _cons | 2.1351     | 1.042775            | 1.55  | 0.120 | .8197749             | 5.560858 |
|       | 1.586014   | 1.939482            | 0.38  | 0.706 | .144345              | 17.42658 |

Note: `_cons` estimates baseline odds.

Also, you can specify `vce(cluster clustvar)` and then, within cluster, relax the assumption of independence. To illustrate this, we have made some fictional additions to the low-birthweight data.

Say that these data are not a random sample of mothers but instead are a random sample of mothers from a random sample of hospitals. In fact, that may be true—we do not know the history of these data.

Hospitals specialize, and it would not be too incorrect to say that some hospitals specialize in more difficult cases. We are going to show two extremes. In one, all hospitals are alike, but we are going to estimate under the possibility that they might differ. In the other, hospitals are strikingly different. In both cases, we assume that patients are drawn from 20 hospitals.

In both examples, we will fit the same model, and we will type the same command to fit it. Below are the same data we have been using but with a new variable, `hospid`, that identifies from which of the 20 hospitals each patient was drawn (and which we have made up):

```
. use https://www.stata-press.com/data/r19/hospid1, clear
. logistic low age lwt i.race smoke ptl ht ui, vce(cluster hospid)
Logistic regression Number of obs = 189
 Wald chi2(8) = 49.67
 Prob > chi2 = 0.0000
Log pseudolikelihood = -100.724 Pseudo R2 = 0.1416
 (Std. err. adjusted for 20 clusters in hospid)
```

| low   | Odds ratio | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|------------|---------------------|-------|-------|----------------------|----------|
| age   | .9732636   | .0397476            | -0.66 | 0.507 | .898396              | 1.05437  |
| lwt   | .9849634   | .0057101            | -2.61 | 0.009 | .9738352             | .9962187 |
| race  |            |                     |       |       |                      |          |
| Black | 3.534767   | 2.013285            | 2.22  | 0.027 | 1.157563             | 10.79386 |
| Other | 2.368079   | .8451325            | 2.42  | 0.016 | 1.176562             | 4.766257 |
| smoke | 2.517698   | .8284259            | 2.81  | 0.005 | 1.321062             | 4.79826  |
| ptl   | 1.719161   | .6676221            | 1.40  | 0.163 | .8030814             | 3.680219 |
| ht    | 6.249602   | 4.066275            | 2.82  | 0.005 | 1.74591              | 22.37086 |
| ui    | 2.1351     | 1.093144            | 1.48  | 0.138 | .7827337             | 5.824014 |
| _cons | 1.586014   | 1.661913            | 0.44  | 0.660 | .2034094             | 12.36639 |

Note: `_cons` estimates baseline odds.

The standard errors are similar to the standard errors we have previously obtained, whether we used the robust or conventional estimators. In this example, we invented the hospital IDs randomly.

Here are the results of the estimation with the same data but with a different set of hospital IDs:

```
. use https://www.stata-press.com/data/r19/hospid2
. logistic low age lwt i.race smoke ptl ht ui, vce(cluster hospid)
Logistic regression Number of obs = 189
 Wald chi2(8) = 7.19
 Prob > chi2 = 0.5167
Log pseudolikelihood = -100.724 Pseudo R2 = 0.1416
 (Std. err. adjusted for 20 clusters in hospid)
```

| low   | Odds ratio | Robust<br>std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|------------|---------------------|-------|-------|----------------------|----------|
| age   | .9732636   | .0293064            | -0.90 | 0.368 | .9174862             | 1.032432 |
| lwt   | .9849634   | .0106123            | -1.41 | 0.160 | .9643817             | 1.005984 |
| race  |            |                     |       |       |                      |          |
| Black | 3.534767   | 3.120338            | 1.43  | 0.153 | .6265521             | 19.9418  |
| Other | 2.368079   | 1.297738            | 1.57  | 0.116 | .8089594             | 6.932114 |
| smoke | 2.517698   | 1.570287            | 1.48  | 0.139 | .7414969             | 8.548655 |
| ptl   | 1.719161   | .6799153            | 1.37  | 0.171 | .7919045             | 3.732161 |
| ht    | 6.249602   | 7.165454            | 1.60  | 0.110 | .660558              | 59.12808 |
| ui    | 2.1351     | 1.411977            | 1.15  | 0.251 | .5841231             | 7.804266 |
| _cons | 1.586014   | 1.946253            | 0.38  | 0.707 | .1431423             | 17.573   |

Note: **\_cons** estimates baseline odds.

Note the strikingly larger standard errors. What happened? In these data, women most likely to have low-birthweight babies are sent to certain hospitals, and the decision on likeliness is based not just on age, smoking history, etc., but on other things that doctors can see but that are not recorded in our data. Thus, merely because a woman is at one of the centers identifies her to be more likely to have a low-birthweight baby.

| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(mns)</code>          | vector of means of the independent variables |
| <code>e(rules)</code>        | information about perfect predictors         |
| <code>e(V)</code>            | variance-covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

### Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

Matrices

`r(table)`

matrix containing the coefficients with their standard errors, test statistics, *p*-values, and confidence intervals

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

Define  $\mathbf{x}_j$  as the (row) vector of independent variables, augmented by 1, and  $\mathbf{b}$  as the corresponding estimated parameter (column) vector. The logistic regression model is fit by `logit`; see [R] `logit` for details of estimation.

The odds ratio corresponding to the *i*th coefficient is  $\psi_i = \exp(b_i)$ . The standard error of the odds ratio is  $s_i^\psi = \psi_i s_i$ , where  $s_i$  is the standard error of  $b_i$  estimated by `logit`.

Define  $I_j = \mathbf{x}_j \mathbf{b}$  as the predicted index of the *j*th observation. The predicted probability of a positive outcome is

$$p_j = \frac{\exp(I_j)}{1 + \exp(I_j)}$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] `_robust`, particularly *Maximum likelihood estimators* and *Methods and formulas*.

`logistic` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] `Variance estimation`.

## Postestimation commands

The following postestimation commands are of special interest after `logistic`:

| Command                           | Description                                                           |
|-----------------------------------|-----------------------------------------------------------------------|
| <code>estat classification</code> | report various summary statistics, including the classification table |
| <code>estat gof</code>            | Pearson or Hosmer–Lemeshow goodness-of-fit test                       |
| <code>lroc</code>                 | compute area under ROC curve and graph the curve                      |
| <code>lsens</code>                | graph sensitivity and specificity versus probability cutoff           |

These commands are not appropriate with `svy` estimation results.

The following standard postestimation commands are also available:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike's, consistent Akaike's, corrected Akaike's, and Schwarz's Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman's specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from <code>margins</code> (profile plots, interaction plots, etc.)                                                    |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | probabilities, influence statistics, residuals, etc.                                                                                    |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results. `forecast` is also not appropriate with `mi` estimation results.

# predict

## Description for predict

`predict` creates a new variable containing predictions such as probabilities, linear predictions, standard errors, influence statistics, deviance residuals, leverages, sequential numbers, Pearson residuals, and the equation-level score.

## Menu for predict

Statistics > Postestimation

## Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset rules asif]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

`pr` probability of a positive outcome; the default

`xb` linear prediction

`stdp` standard error of the prediction

\* `dbeta` Pregibon (1981)  $\Delta \hat{\beta}$  influence statistic

\* `deviance` deviance residual

\* `dx2` Hosmer, Lemeshow, and Sturdivant (2013)  $\Delta \chi^2$  influence statistic

\* `ddeviance` Hosmer, Lemeshow, and Sturdivant (2013)  $\Delta D$  influence statistic

\* `hat` Pregibon (1981) leverage

\* `number` sequential number of the covariate pattern

\* `residuals` Pearson residuals; adjusted for number sharing covariate pattern

\* `rstandard` standardized Pearson residuals; adjusted for number sharing covariate pattern

`score` first derivative of the log likelihood with respect to  $\mathbf{x}_j\beta$

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

`pr`, `xb`, `stdp`, and `score` are the only options allowed with `svy` estimation results.

## Options for predict

## Main

`pr`, the default, calculates the probability of a positive outcome.

`xb` calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`dbeta` calculates the Pregibon (1981)  $\Delta\hat{\beta}$  influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation along with all others that share the same covariate pattern. In Hosmer, Lemeshow, and Sturdivant (2013, 154–155) jargon, this statistic is *M*-asymptotic; that is, it is adjusted for the number of observations that share the same covariate pattern.

`deviance` calculates the deviance residual.

`dx2` calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191)  $\Delta\chi^2$  influence statistic, reflecting the decrease in the Pearson  $\chi^2$  that is due to deletion of the observation and all others that share the same covariate pattern.

`ddeviance` calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191)  $\Delta D$  influence statistic, which is the change in the deviance residual that is due to deletion of the observation and all others that share the same covariate pattern.

`hat` calculates the Pregibon (1981) leverage or the diagonal elements of the hat matrix adjusted for the number of observations that share the same covariate pattern.

`number` numbers the covariate patterns—observations with the same covariate pattern have the same number. Observations not used in estimation have `number` set to missing. The first covariate pattern is numbered 1, the second 2, and so on.

`residuals` calculates the Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 155) and adjusted for the number of observations that share the same covariate pattern.

`rstandard` calculates the standardized Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 191) and adjusted for the number of observations that share the same covariate pattern.

`score` calculates the equation-level score,  $\partial \ln L / \partial (\mathbf{x}_j \boldsymbol{\beta})$ .

## Options

`nooffset` is relevant only if you specified `offset(varname)` for `logistic`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j \mathbf{b}$  rather than as  $\mathbf{x}_j \mathbf{b} + \text{offset}_j$ .

`rules` requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations. See [example 1](#) in [R] [logit postestimation](#).

`asif` requests that Stata ignore the rules and the exclusion criteria and calculate predictions for all observations possible by using the estimated parameter from the model. See [example 1](#) in [R] [logit postestimation](#).

# margins

## Description for margins

`margins` estimates margins of response for probabilities and linear predictions.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
```

```
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>       | Description                                    |
|------------------------|------------------------------------------------|
| <code>pr</code>        | probability of a positive outcome; the default |
| <code>xb</code>        | linear prediction                              |
| <code>stdp</code>      | not allowed with margins                       |
| <code>dbeta</code>     | not allowed with margins                       |
| <code>deviance</code>  | not allowed with margins                       |
| <code>dx2</code>       | not allowed with margins                       |
| <code>ddeviance</code> | not allowed with margins                       |
| <code>hat</code>       | not allowed with margins                       |
| <code>number</code>    | not allowed with margins                       |
| <code>residuals</code> | not allowed with margins                       |
| <code>rstandard</code> | not allowed with margins                       |
| <code>score</code>     | not allowed with margins                       |

Statistics not allowed with margins are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [\[R\] margins](#).

## Remarks and examples

`predict` is used after `logistic` to obtain predicted probabilities, residuals, and influence statistics for the estimation sample. The suggested diagnostic graphs below are from [Hosmer, Lemeshow, and Sturdivant \(2013\)](#), where they are more elaborately explained. Also see [Collett \(2003, 129–168\)](#) for a thorough discussion of model checking.

Remarks are presented under the following headings:

*predict without options*  
*predict with the xb and stdp options*  
*predict with the residuals option*  
*predict with the number option*  
*predict with the deviance option*  
*predict with the rstandard option*  
*predict with the hat option*  
*predict with the dx2 option*  
*predict with the ddeviance option*  
*predict with the dbeta option*

### predict without options

Typing `predict newvar` after estimation calculates the predicted probability of a positive outcome.

In [example 1](#) of [\[R\] logistic](#), we ran the model `logistic low age lwt i.race smoke ptl ht ui`. We obtain the predicted probabilities of a positive outcome by typing

```
. use https://www.stata-press.com/data/r19/lbw
(Hosmer & Lemeshow data)
. logistic low age lwt i.race smoke ptl ht ui
(output omitted)
. predict p
(option pr assumed; Pr(low))
. summarize p low
```

| Variable | Obs | Mean     | Std. dev. | Min      | Max      |
|----------|-----|----------|-----------|----------|----------|
| p        | 189 | .3121693 | .1913915  | .0272559 | .8391283 |
| low      | 189 | .3121693 | .4646093  | 0        | 1        |

### predict with the xb and stdp options

`predict` with the `xb` option calculates the linear combination  $x_j\mathbf{b}$ , where  $x_j$  are the independent variables in the  $j$ th observation and  $\mathbf{b}$  is the estimated parameter vector. This is sometimes known as the index function because the cumulative distribution function indexed at this value is the probability of a positive outcome.

With the `stdp` option, `predict` calculates the standard error of the prediction, which is *not* adjusted for replicated covariate patterns in the data. The influence statistics described below are adjusted for replicated covariate patterns in the data.

## predict with the residuals option

`predict` can calculate more than predicted probabilities. The Pearson residual is defined as the square root of the contribution of the covariate pattern to the Pearson  $\chi^2$  goodness-of-fit statistic, signed according to whether the observed number of positive responses within the covariate pattern is less than or greater than expected. For instance,

```
. predict r, residuals
. summarize r, detail
```

| Pearson residual |             |           |             |  |           |
|------------------|-------------|-----------|-------------|--|-----------|
|                  | Percentiles | Smallest  |             |  |           |
| 1%               | -1.750923   | -2.283885 |             |  |           |
| 5%               | -1.129907   | -1.750923 |             |  |           |
| 10%              | -.9581174   | -1.636279 | Obs         |  | 189       |
| 25%              | -.6545911   | -1.636279 | Sum of wgt. |  | 189       |
| 50%              | -.3806923   |           | Mean        |  | -.0242299 |
|                  |             | Largest   | Std. dev.   |  | .9970949  |
| 75%              | .8162894    | 2.23879   |             |  |           |
| 90%              | 1.510355    | 2.317558  | Variance    |  | .9941981  |
| 95%              | 1.747948    | 3.002206  | Skewness    |  | .8618271  |
| 99%              | 3.002206    | 3.126763  | Kurtosis    |  | 3.038448  |

We notice the prevalence of a few large positive residuals:

```
. sort r
. list id r low p age race in -5/1
```

|      | id | r        | low | p        | age | race  |
|------|----|----------|-----|----------|-----|-------|
| 185. | 33 | 2.224501 | 1   | .1681123 | 19  | White |
| 186. | 57 | 2.23879  | 1   | .166329  | 15  | White |
| 187. | 16 | 2.317558 | 1   | .1569594 | 27  | Other |
| 188. | 77 | 3.002206 | 1   | .0998678 | 26  | White |
| 189. | 36 | 3.126763 | 1   | .0927932 | 24  | White |

## predict with the number option

Covariate patterns play an important role in logistic regression. Two observations are said to share the same covariate pattern if the independent variables for the two observations are identical. Although we might think of having individual observations, the statistical information in the sample can be summarized by the covariate patterns, the number of observations with that covariate pattern, and the number of positive outcomes within the pattern. Depending on the model, the number of covariate patterns can approach or be equal to the number of observations, or it can be considerably less.

Stata calculates all the residual and diagnostic statistics in terms of covariate patterns, not observations. That is, all observations with the same covariate pattern are given the same residual and diagnostic statistics. Hosmer, Lemeshow, and Sturdivant (2013, 154–155) argue that such “*M*-asymptotic” statistics are more useful than “*N*-asymptotic” statistics.

To understand the difference, think of an observed positive outcome with predicted probability of 0.8. Taking the observation in isolation, the residual must be positive—we expected 0.8 positive responses and observed 1. This may indeed be the correct residual, but not necessarily. Under the *M*-asymptotic definition, we ask how many successes we observed across all observations with this covariate pattern.

If that number were, say, six, and there were a total of 10 observations with this covariate pattern, then the residual is negative for the covariate pattern—we expected eight positive outcomes but observed six. `predict` makes this kind of calculation and then attaches the same residual to all observations in the covariate pattern.

Occasionally, you might want to find all observations sharing a covariate pattern. `number` allows you to do this:

```
. predict pattern, number
. summarize pattern
```

| Variable | Obs | Mean    | Std. dev. | Min | Max |
|----------|-----|---------|-----------|-----|-----|
| pattern  | 189 | 89.2328 | 53.16573  | 1   | 182 |

We previously fit the model `logistic low age lwt i.race smoke ptl ht ui` over 189 observations. There are 182 covariate patterns in our data.

### predict with the deviance option

The deviance residual is defined as the square root of the contribution to the likelihood-ratio test statistic of a saturated model versus the fitted model. It has slightly different properties from the Pearson residual (see [Hosmer, Lemeshow, and Sturdivant \[2013, 155–157\]](#)):

```
. predict d, deviance
. summarize d, detail
```

| deviance residual |             |           |             |  |           |
|-------------------|-------------|-----------|-------------|--|-----------|
|                   | Percentiles | Smallest  |             |  |           |
| 1%                | -1.843472   | -1.911621 |             |  |           |
| 5%                | -1.33477    | -1.843472 |             |  |           |
| 10%               | -1.148316   | -1.843472 | Obs         |  | 189       |
| 25%               | -.8445325   | -1.674869 | Sum of wgt. |  | 189       |
| 50%               | -.5202702   |           | Mean        |  | -.1228811 |
|                   |             | Largest   | Std. dev.   |  | 1.049237  |
| 75%               | .9129041    | 1.894089  |             |  |           |
| 90%               | 1.541558    | 1.924457  | Variance    |  | 1.100898  |
| 95%               | 1.673338    | 2.146583  | Skewness    |  | .6598857  |
| 99%               | 2.146583    | 2.180542  | Kurtosis    |  | 2.036938  |

## predict with the rstandard option

Pearson residuals do not have a standard deviation equal to 1. `rstandard` generates Pearson residuals normalized to have an *expected* standard deviation equal to 1.

```
. predict rs, rstandard
. summarize r rs
```

| Variable | Obs | Mean      | Std. dev. | Min       | Max      |
|----------|-----|-----------|-----------|-----------|----------|
| r        | 189 | -.0242299 | .9970949  | -2.283885 | 3.126763 |
| rs       | 189 | -.0279135 | 1.026406  | -2.4478   | 3.149081 |

```
. correlate r rs
(obs=189)
```

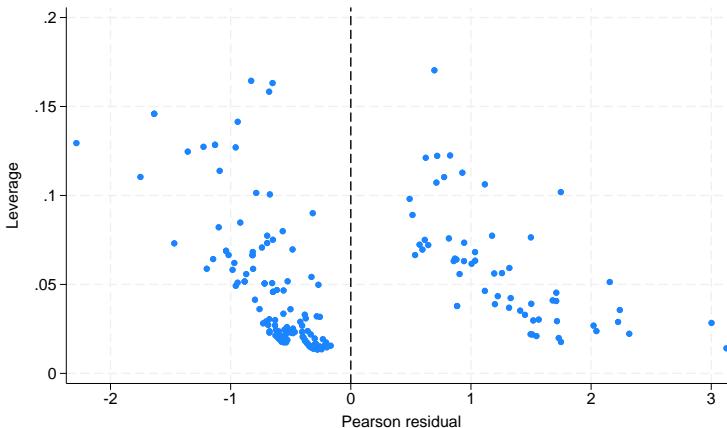

|    | r      | rs     |
|----|--------|--------|
| r  | 1.0000 |        |
| rs | 0.9998 | 1.0000 |

Remember that we previously created `r` containing the (unstandardized) Pearson residuals. In these data, whether we use standardized or unstandardized residuals does not matter much.

## predict with the hat option

`hat` calculates the leverage of a covariate pattern—a scaled measure of distance in terms of the independent variables. Large values indicate covariate patterns far from the average covariate pattern that can have a large effect on the fitted model even if the corresponding residual is small. Consider the following graph:

```
. predict h, hat
. scatter h r, xline(0) ytitle("Leverage")
```

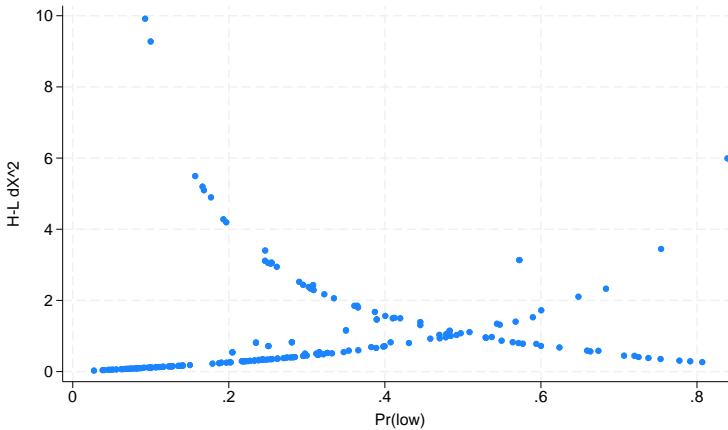

The points to the left of the vertical line are observed negative outcomes; here our data contain almost as many covariate patterns as observations, so most covariate patterns are unique. In such unique patterns, we observe either 0 or 1 success and expect  $p$ , thus forcing the sign of the residual. If we had fewer covariate patterns—if we did not have continuous variables in our model—there would be no such interpretation, and we would not have drawn the vertical line at 0.

Points on the left and right edges of the graph represent large residuals—covariate patterns that are not fit well by our model. Points at the top of our graph represent high leverage patterns. When analyzing the influence of observations on the model, we are most interested in patterns with high leverage and small residuals—patterns that might otherwise escape our attention.

## predict with the dx2 option

There are many ways to measure influence, and `hat` is one example. `dx2` measures the decrease in the Pearson  $\chi^2$  goodness-of-fit statistic that would be caused by deleting an observation (and all others sharing the covariate pattern):

```
. predict dx2, dx2
. scatter dx2 p
```

Paraphrasing [Hosmer, Lemeshow, and Sturdivant \(2013, 195–197\)](#), the points going from the top left to the bottom right correspond to covariate patterns with the number of positive outcomes equal to the number in the group; the points on the other curve correspond to 0 positive outcomes. In our data, most of the covariate patterns are unique, so the points tend to lie along one or the other curves; the points that are off the curves correspond to the few repeated covariate patterns in our data in which all the outcomes are not the same.

We examine this graph for large values of `dx2`—there are two at the top left.

## predict with the ddeviance option

Another measure of influence is the change in the deviance residuals due to deletion of a covariate pattern:

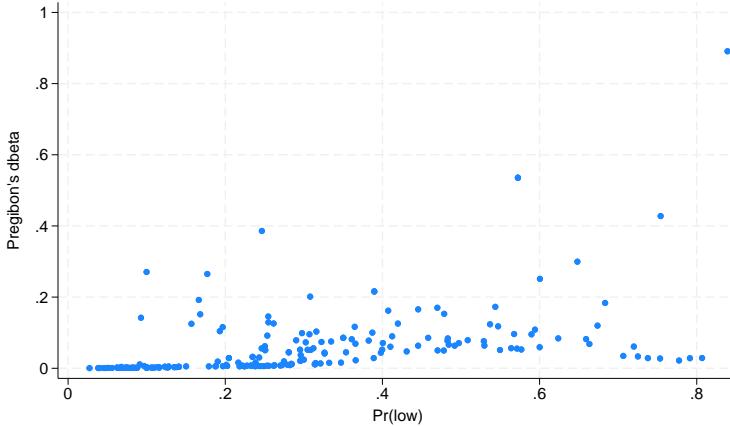

```
. predict dd, ddeviance
```

As with `dx2`, we typically graph `ddeviance` against the probability of a positive outcome. We direct you to [Hosmer, Lemeshow, and Sturdivant \(2013, 195\)](#) for an example and for the interpretation of this graph.

## predict with the dbeta option

One of the more direct measures of influence of interest to model fitters is the [Pregibon \(1981\)](#) dbeta measure, a measure of the change in the coefficient vector that would be caused by deleting an observation (and all others sharing the covariate pattern):

```
. predict db, dbeta
. scatter db p
```

One observation has a large effect on the estimated coefficients. We can easily find this point:

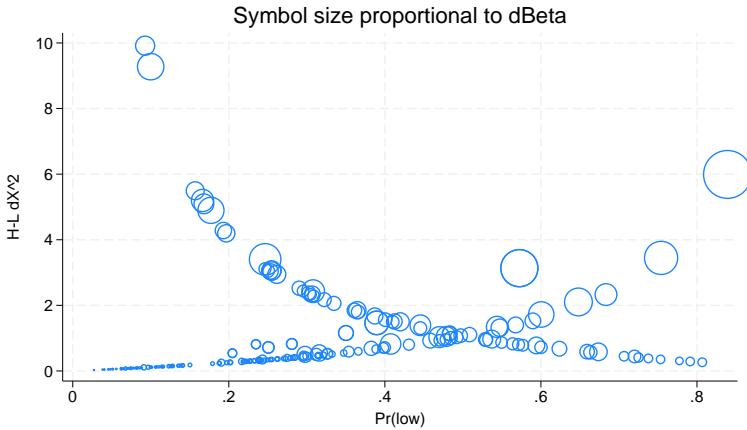

```
. sort db
. list in 1
```

189.

|          |     |           |     |          |           |     |          |    |          |      |
|----------|-----|-----------|-----|----------|-----------|-----|----------|----|----------|------|
| id       | low | age       | lwt | race     | smoke     | ptl | ht       | ui | ftv      | bwt  |
| 188      | 0   | 25        | 95  | White    | Smoker    | 3   | 0        | 1  | 0        | 3637 |
| p        |     | r         |     | pattern  | d         |     | rs       |    | h        |      |
| .8391283 |     | -2.283885 |     | 117      | -1.911621 |     | -2.4478  |    | .1294439 |      |
| dx2      |     |           |     | dd       |           |     | db       |    |          |      |
| 5.991726 |     |           |     | 4.197658 |           |     | .8909163 |    |          |      |

Hosmer, Lemeshow, and Sturdivant (2013, 196) suggest a graph that combines two of the influence measures:

```
. scatter dx2 p [aw=db], title("Symbol size proportional to dBeta") mfcolor(none)
```

We can easily spot the most influential points by the dbeta and dx2 measures.

## Methods and formulas

Let  $j$  index observations. Define  $M_j$  for each observation as the total number of observations sharing  $j$ 's covariate pattern. Define  $Y_j$  as the total number of positive responses among observations sharing  $j$ 's covariate pattern.

The Pearson residual for the  $j$ th observation is defined as

$$r_j = \frac{Y_j - M_j p_j}{\sqrt{M_j p_j (1 - p_j)}}$$

For  $M_j > 1$ , the deviance residual  $d_j$  is defined as

$$d_j = \pm \left( 2 \left[ Y_j \ln \left( \frac{Y_j}{M_j p_j} \right) + (M_j - Y_j) \ln \left\{ \frac{M_j - Y_j}{M_j (1 - p_j)} \right\} \right] \right)^{1/2}$$

where the sign is the same as the sign of  $(Y_j - M_j p_j)$ . In the limiting cases, the deviance residual is given by

$$d_j = \begin{cases} -\sqrt{2M_j |\ln(1 - p_j)|} & \text{if } Y_j = 0 \\ \sqrt{2M_j |\ln p_j|} & \text{if } Y_j = M_j \end{cases}$$

The *unadjusted* diagonal elements of the hat matrix  $h_{Uj}$  are given by  $h_{Uj} = (\mathbf{XVX}')_{jj}$ , where  $V$  is the estimated covariance matrix of parameters. The adjusted diagonal elements  $h_j$  created by hat are then  $h_j = M_j p_j (1 - p_j) h_{Uj}$ .

The standardized Pearson residual  $r_{Sj}$  is  $r_j / \sqrt{1 - h_j}$ .

The Pregibon (1981)  $\Delta\hat{\beta}_j$  influence statistic is

$$\Delta\hat{\beta}_j = \frac{r_j^2 h_j}{(1 - h_j)^2}$$

The corresponding change in the Pearson  $\chi^2$  is  $r_{Sj}^2$ . The corresponding change in the deviance residual is  $\Delta D_j = d_j^2 / (1 - h_j)$ .

## Description

`logit` fits a logit model for a binary response by maximum likelihood; it models the probability of a positive outcome given a set of regressors. `devar` equal to nonzero and nonmissing (typically `devar` equal to one) indicates a positive outcome, whereas `devar` equal to zero indicates a negative outcome.

Also see [\[R\] `logistic`](#); `logistic` displays estimates as odds ratios. Many users prefer the `logistic` command to `logit`. Results are the same regardless of which you use—both are the maximum-likelihood estimator. Several auxiliary commands that can be run after `logit`, `probit`, or `logistic` estimation are described in [\[R\] `logistic postestimation`](#).

## Quick start

Logit model of `y` on `x1` and `x2`

```
logit y x1 x2
```

Add indicators for categorical variable `a`

```
logit y x1 x2 i.a
```

With cluster-robust standard errors for clustering by levels of `cvar`

```
logit y x1 x2 i.a, vce(cluster cvar)
```

Save separate coefficient estimates for each level of `cvar` to `myresults.dta`

```
statsby _b, by(cvar) saving(myresults): logit y x1 x2 i.a
```

Adjust for complex survey design using `svyset` data

```
svy: logit y x1 x2 i.a
```

## Menu

Statistics > Binary outcomes > Logistic regression

## Syntax

```
logit deprvar [indepvars] [if] [in] [weight] [, options]
```

*indepvars* may contain factor variables; see [U] 11.4.3 **Factor variables**.

*deprvar* and *indepvars* may contain time-series operators; see [U] 11.4.4 **Time-series varlists**.

`bayes`, `bayesboot`, `bootstrap`, `by`, `collect`, `fmm`, `fp`, `jackknife`, `mfp`, `mi estimate`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 **Prefix commands**. For more details, see [BAYES] **bayes: logit** and [FMM] **fmm: logit**.

`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] **mi estimate**.

Weights are not allowed with the `bootstrap` prefix; see [R] **bootstrap**.

`vce()`, `nocoeff`, and `weights` are not allowed with the `svy` prefix; see [SVY] **svy**.

`fweights`, `iwweights`, and `pweights` are allowed; see [U] 11.1.6 **weight**.

`nocoeff`, `collinear`, and `coeflegend` do not appear in the dialog box.

See [U] 20 **Estimation and postestimation commands** for more capabilities of estimation commands.

## Options

### Model

`noconstant`, `offset(varname)`, `constraints(constraints)`; see [R] [Estimation options](#).

`asis` forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] [probit](#).

### SE/Robust

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`, `opg`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] [vce\\_option](#).

### Reporting

`level(#)`; see [R] [Estimation options](#).

`or` reports the estimated coefficients transformed to odds ratios, that is,  $e^b$  rather than  $b$ . Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. `or` may be specified at estimation or when replaying previously estimated results.

`nocnsreport`; see [R] [Estimation options](#).

`display_options`: `nocl`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] [Estimation options](#).

### Maximization

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log`, `trace`, `gradient`, `showstep`, `hessian`, `showtolerance`, `tolerance(#)`, `ltolerance(#)`, `nrtolerance(#)`, `nonrtolerance`, and `from(init_specs)`; see [R] [Maximize](#). These options are seldom used.

The following options are available with `logit` but are not shown in the dialog box:

`noccoef` specifies that the coefficient table not be displayed. This option is sometimes used by program writers but is of no use interactively.

`collinear`, `coeflegend`; see [R] [Estimation options](#).

## Remarks and examples

Remarks are presented under the following headings:

*Basic usage*

*Model identification*

## Basic usage

`logit` fits maximum likelihood models with dichotomous dependent (left-hand-side) variables coded as 0/1 (or, more precisely, coded as 0 and not-0).

For grouped data or data in binomial form, a probit model can be fit using `glm` with the family(binomial) and link(logit) options.

### ► Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a logit model explaining whether a car is foreign on the basis of its weight and mileage. Here is an overview of our data:

```
. use https://www.stata-press.com/data/r19/aut
(1978 automobile data)
. keep make mpg weight foreign
. describe
Contains data from https://www.stata-press.com/data/r19/aut.dta
Observations: 74 1978 automobile data
Variables: 4 13 Apr 2024 17:45
 (_dta has notes)
```

| Variable name | Storage type | Display format | Value label | Variable label |
|---------------|--------------|----------------|-------------|----------------|
| make          | str18        | %-18s          |             | Make and model |
| mpg           | int          | %8.0g          |             | Mileage (mpg)  |
| weight        | int          | %8.0gc         |             | Weight (lbs.)  |
| foreign       | byte         | %8.0g          | origin      | Car origin     |

Sorted by: foreign

Note: Dataset has changed since last saved.

```
. inspect foreign
```

| foreign: Car origin |          | Number of observations |          |             |
|---------------------|----------|------------------------|----------|-------------|
|                     |          | Total                  | Integers | Nonintegers |
| #                   | Negative | -                      | -        | -           |
| #                   | Zero     | 52                     | 52       | -           |
| #                   | Positive | 22                     | 22       | -           |
| #                   |          |                        |          |             |
| # #                 | Total    | 74                     | 74       | -           |
| # #                 | Missing  | -                      |          |             |
| 0                   |          | 74                     |          |             |
| 1                   |          |                        |          |             |

(2 unique values)

foreign is labeled and all values are documented in the label.

The variable `foreign` takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

$$\Pr(\text{foreign} = 1) = F(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg})$$

where  $F(z) = e^z / (1 + e^z)$  is the cumulative logistic distribution.

To fit this model, we type

```
. logit foreign weight mpg
Iteration 0: Log likelihood = -45.03321
Iteration 1: Log likelihood = -29.238536
Iteration 2: Log likelihood = -27.244139
Iteration 3: Log likelihood = -27.175277
Iteration 4: Log likelihood = -27.175156
Iteration 5: Log likelihood = -27.175156

Logistic regression Number of obs = 74
 LR chi2(2) = 35.72
 Prob > chi2 = 0.0000
Log likelihood = -27.175156 Pseudo R2 = 0.3966
```

| foreign | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|---------|-------------|-----------|-------|-------|----------------------|----------|
| weight  | -.0039067   | .0010116  | -3.86 | 0.000 | -.0058894            | -.001924 |
| mpg     | -.1685869   | .0919175  | -1.83 | 0.067 | -.3487418            | .011568  |
| _cons   | 13.70837    | 4.518709  | 3.03  | 0.002 | 4.851859             | 22.56487 |

We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least holding the weight of the car constant.

◀

## □ Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type `logit y x`, Stata fits the model

$$\Pr(y_j \neq 0 \mid \mathbf{x}_j) = \frac{\exp(\mathbf{x}_j\boldsymbol{\beta})}{1 + \exp(\mathbf{x}_j\boldsymbol{\beta})}$$

□

## Model identification

The `logit` command has one more feature, and it is probably the most useful. `logit` automatically checks the model for identification and, if it is underidentified, drops whatever variables and observations are necessary for estimation to proceed. (`logistic`, `probit`, and `ivprobit` do this as well.)

## ▶ Example 2

Have you ever fit a logit model where one or more of your independent variables perfectly predicted one or the other outcome?

For instance, consider the following data:

| Outcome $y$ | Independent variable $x$ |
|-------------|--------------------------|
| 0           | 1                        |
| 0           | 1                        |
| 0           | 0                        |
| 1           | 0                        |

Say that we wish to predict the outcome on the basis of the independent variable. The outcome is always zero whenever the independent variable is one. In our data,  $\Pr(y = 0 \mid x = 1) = 1$ , which means that the logit coefficient on  $x$  must be minus infinity with a corresponding infinite standard error. At this point, you may suspect that we have a problem.

Unfortunately, not all such problems are so easily detected, especially if you have a lot of independent variables in your model. If you have ever had such difficulties, you have experienced one of the more unpleasant aspects of computer optimization. The computer has no idea that it is trying to solve for an infinite coefficient as it begins its iterative process. All it knows is that at each step, making the coefficient a little bigger, or a little smaller, works wonders. It continues on its merry way until either 1) the whole thing comes crashing to the ground when a numerical overflow error occurs or 2) it reaches some predetermined cutoff that stops the process. In the meantime, you have been waiting. The estimates that you finally receive, if you receive any at all, may be nothing more than numerical roundoff.

Stata watches for these sorts of problems, alerts us, fixes them, and properly fits the model.

Let's return to our automobile data. Among the variables we have in the data is one called `repair`, which takes on three values. A value of 1 indicates that the car has a poor repair record, 2 indicates an average record, and 3 indicates a better-than-average record. Here is a tabulation of our data:

```
. use https://www.stata-press.com/data/r19/repair, clear
(1978 automobile data)
. tabulate foreign repair
```

| Car origin | Repair |    |    | Total |
|------------|--------|----|----|-------|
|            | 1      | 2  | 3  |       |
| Domestic   | 10     | 27 | 9  | 46    |
| Foreign    | 0      | 3  | 9  | 12    |
| Total      | 10     | 30 | 18 | 58    |

All the cars with poor repair records (`repair = 1`) are domestic. If we were to attempt to predict `foreign` on the basis of the repair records, the predicted probability for the `repair = 1` category would have to be zero. This in turn means that the logit coefficient must be minus infinity, and that would set most computer programs buzzing.

Let's try Stata on this problem.

```
. logit foreign b3.repair
note: 1.repair != 0 predicts failure perfectly;
 1.repair omitted and 10 obs not used.
Iteration 0: Log likelihood = -26.992087
Iteration 1: Log likelihood = -22.483187
Iteration 2: Log likelihood = -22.230498
Iteration 3: Log likelihood = -22.229139
Iteration 4: Log likelihood = -22.229138

Logistic regression Number of obs = 48
 LR chi2(1) = 9.53
 Prob > chi2 = 0.0020
 Pseudo R2 = 0.1765

Log likelihood = -22.229138
```

|  | foreign | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |           |
|--|---------|-------------|-----------|-------|-------|----------------------|-----------|
|  | repair  |             |           |       |       |                      |           |
|  | 1       | 0           | (empty)   |       |       |                      |           |
|  | 2       | -2.197225   | .7698003  | -2.85 | 0.004 | -3.706005            | -.6884436 |
|  | _cons   | -1.85e-17   | .4714045  | -0.00 | 1.000 | -.9239359            | .9239359  |

Remember that all the cars with poor repair records (`repair = 1`) are domestic, so the model cannot be fit, or at least it cannot be fit if we restrict ourselves to finite coefficients. Stata noted that fact “note: 1.repair !=0 predicts failure perfectly”. This is Stata’s mathematically precise way of saying what we said in English. When `repair` is 1, the car is domestic.

Stata then went on to say “1.repair omitted and 10 obs not used”. This is Stata eliminating the problem. First `1.repair` had to be removed from the model because it would have an infinite coefficient. Then, the 10 observations that led to the problem had to be eliminated, as well, so as not to bias the remaining coefficients in the model. The 10 observations that are not used are the 10 domestic cars that have poor repair records.

Stata then fit what was left of the model, using the remaining observations. Because no observations remained for cars with poor repair records, Stata reports “(empty)” in the row for `repair = 1`.

## □ Technical note

Stata is pretty smart about catching problems like this. It will catch “one-way causation by a dummy variable”, as we demonstrated above.

Stata also watches for “two-way causation”, that is, a variable that perfectly determines the outcome, both successes and failures. Here Stata says, “so-and-so predicts outcome perfectly” and stops. Statistics dictates that no model can be fit.

Stata also checks your data for collinear variables; it will say, “so-and-so omitted because of collinearity”. No observations need to be eliminated in this case, and model fitting will proceed without the offending variable.

It will also catch a subtle problem that can arise with continuous data. For instance, if we were estimating the chances of surviving the first year after an operation, and if we included in our model age, and if all the persons over 65 died within the year, Stata would say, “age > 65 predicts failure perfectly”. It would then inform us about the fix-up it takes and fit what can be fit of our model.

logit (and logistic, probit, and ivprobit) will also occasionally display messages such as

Note: 4 failures and 0 successes completely determined.

There are two causes for a message like this. The first—and most unlikely—case occurs when a continuous variable (or a combination of a continuous variable with other continuous or dummy variables) is simply a great predictor of the dependent variable. Consider Stata’s auto.dta dataset with 6 observations removed.

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. drop if foreign==0 & gear_ratio > 3.1
(6 observations deleted)
. logit foreign mpg weight gear_ratio, nolog
Logistic regression Number of obs = 68
 LR chi2(3) = 72.64
 Prob > chi2 = 0.0000
Log likelihood = -6.4874814 Pseudo R2 = 0.8484
```

| foreign    | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|------------|-------------|-----------|-------|-------|----------------------|----------|
| mpg        | -.4944907   | .2655508  | -1.86 | 0.063 | -1.014961            | .0259792 |
| weight     | -.0060919   | .003101   | -1.96 | 0.049 | -.0121698            | -.000014 |
| gear_ratio | 15.70509    | 8.166234  | 1.92  | 0.054 | -.300436             | 31.71061 |
| _cons      | -21.39527   | 25.41486  | -0.84 | 0.400 | -71.20747            | 28.41694 |

Note: 4 failures and 0 successes completely determined.

There are no missing standard errors in the output. If you receive the “completely determined” message and have one or more missing standard errors in your output, see the second case discussed below.

Note gear\_ratio’s large coefficient. logit thought that the 4 observations with the smallest predicted probabilities were essentially predicted perfectly.

```
. predict p
(option pr assumed; Pr(foreign))
. sort p
. list p in 1/4
```

|    | P        |
|----|----------|
| 1. | 1.34e-10 |
| 2. | 6.26e-09 |
| 3. | 7.84e-09 |
| 4. | 1.49e-08 |

If this happens to you, you do not have to do anything. Computationally, the model is sound. The second case discussed below requires careful examination.

The second case occurs when the independent terms are all dummy variables or continuous ones with repeated values (for example, age). Here one or more of the estimated coefficients will have missing standard errors. For example, consider this dataset consisting of 6 observations.

```
. use https://www.stata-press.com/data/r19/logitxmpl, clear
. list, separator(0)
```

|    | y | x1 | x2 |
|----|---|----|----|
| 1. | 0 | 0  | 0  |
| 2. | 0 | 0  | 0  |
| 3. | 0 | 1  | 0  |
| 4. | 1 | 1  | 0  |
| 5. | 0 | 0  | 1  |
| 6. | 1 | 0  | 1  |

```

|--|-------|-------------|-----------|--------|-------|----------------------|----------|
|  | x1    | 18.3704     | 2         | 9.19   | 0.000 | 14.45047             | 22.29033 |
|  | x2    | 18.3704     | .         | .      | .     | .                    | .        |
|  | _cons | -18.3704    | 1.414214  | -12.99 | 0.000 | -21.14221            | -15.5986 |

```
Note: 2 failures and 0 successes completely determined.
convergence not achieved
r(430);
```

Three things are happening here. First, `logit` iterates almost forever and then declares nonconvergence. Second, `logit` can fit the outcome ( $y = 0$ ) for the covariate pattern  $x_1 = 0$  and  $x_2 = 0$  (that is, the first two observations) perfectly. This observation is the “2 failures and 0 successes completely determined”. Third, if this observation is excluded, then  $x_1$ ,  $x_2$ , and the constant are collinear.

This is the cause of the nonconvergence, the message “completely determined”, and the missing standard errors. It happens when you have a covariate pattern (or patterns) with only one outcome and there is collinearity when the observations corresponding to this covariate pattern are excluded.

If this happens to you, confirm the causes. First, identify the covariate pattern with only one outcome. (For your data, replace `x1` and `x2` with the independent variables of your model.)

```
. egen pattern = group(x1 x2)
. quietly logit y x1 x2, iterate(100)
convergence not achieved
. predict p
(option pr assumed; Pr(y))
. summarize p
```

| Variable | Obs | Mean     | Std. dev. | Min      | Max |
|----------|-----|----------|-----------|----------|-----|
| p        | 6   | .3333333 | .2581989  | 1.05e-08 | .5  |

If successes were completely determined, that means that there are predicted probabilities that are almost 1. If failures were completely determined, that means that there are predicted probabilities that are almost 0. The latter is the case here, so we locate the corresponding value of `pattern`:

```
. tabulate pattern if p < 1e-7
```

| group(x1<br>x2) | Freq. | Percent | Cum.   |
|-----------------|-------|---------|--------|
| 1               | 2     | 100.00  | 100.00 |
| Total           | 2     | 100.00  |        |

Once we omit this covariate pattern from the estimation sample, `logit` can deal with the collinearity:

```
. logit y x1 x2 if pattern != 1, nolog
note: x2 omitted because of collinearity.
```

```
Logistic regression
```

```
Number of obs = 4
LR chi2(1) = 0.00
Prob > chi2 = 1.0000
Pseudo R2 = 0.0000
```

```
Log likelihood = -2.7725887
```

| y     | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-------|-------------|-----------|------|-------|----------------------|----------|
| x1    | 0           | 2         | 0.00 | 1.000 | -3.919928            | 3.919928 |
| x2    | 0 (omitted) |           |      |       |                      |          |
| _cons | 0           | 1.414214  | 0.00 | 1.000 | -2.771808            | 2.771808 |

We omit the collinear variable. Then we must decide whether to include or omit the observations with `pattern = 1`. We could include them,

```
. logit y x1, nolog
Logistic regression Number of obs = 6
 LR chi2(1) = 0.37
 Prob > chi2 = 0.5447
Log likelihood = -3.6356349 Pseudo R2 = 0.0480
```

| y     | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|-------------|-----------|-------|-------|----------------------|----------|
| x1    | 1.098612    | 1.825742  | 0.60  | 0.547 | -2.479776            | 4.677001 |
| _cons | -1.098612   | 1.154701  | -0.95 | 0.341 | -3.361784            | 1.164559 |

or exclude them,

```
. logit y x1 if pattern != 1, nolog
Logistic regression Number of obs = 4
 LR chi2(1) = 0.00
 Prob > chi2 = 1.0000
Log likelihood = -2.7725887 Pseudo R2 = 0.0000
```

| y     | Coefficient | Std. err. | z    | P> z  | [95% conf. interval] |          |
|-------|-------------|-----------|------|-------|----------------------|----------|
| x1    | 0           | 2         | 0.00 | 1.000 | -3.919928            | 3.919928 |
| _cons | 0           | 1.414214  | 0.00 | 1.000 | -2.771808            | 2.771808 |

If the covariate pattern that predicts outcome perfectly is meaningful, you may want to exclude these observations from the model. Here you would report that covariate pattern such and such predicted outcome perfectly and that the best model for the rest of the data is .... But, more likely, the perfect prediction was simply the result of having too many predictors in the model. Then you would omit the extraneous variables from further consideration and report the best model for all the data.

□

## Stored results

`logit` stores the following in `e()`:

Scalars

|                            |                                           |
|----------------------------|-------------------------------------------|

## Matrices

|                              |                                              |
|------------------------------|----------------------------------------------|
| <code>e(b)</code>            | coefficient vector                           |
| <code>e(Cns)</code>          | constraints matrix                           |
| <code>e(ilog)</code>         | iteration log (up to 20 iterations)          |
| <code>e(gradient)</code>     | gradient vector                              |
| <code>e(mns)</code>          | vector of means of the independent variables |
| <code>e(rules)</code>        | information about perfect predictors         |
| <code>e(V)</code>            | variance–covariance matrix of the estimators |
| <code>e(V_modelbased)</code> | model-based variance                         |

## Functions

|                        |                         |
|------------------------|-------------------------|
| <code>e(sample)</code> | marks estimation sample |
|------------------------|-------------------------|

In addition to the above, the following is stored in `r()`:

## Matrices

|                       |                                                                                                                            |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|
| <code>r(table)</code> | matrix containing the coefficients with their standard errors, test statistics, <i>p</i> -values, and confidence intervals |
|-----------------------|----------------------------------------------------------------------------------------------------------------------------|

Note that results stored in `r()` are updated when the command is replayed and will be replaced when any *r*-class command is run after the estimation command.

## Methods and formulas

Cramer (2003, chap. 9) surveys the prehistory and history of the logit model. The word “logit” was coined by Berkson (1944) and is analogous to the word “probit”. For an introduction to probit and logit, see, for example, Aldrich and Nelson (1984), Cameron and Trivedi (2022), Jones (2007), Long (1997), Long and Freese (2014), Pampel (2021), or Powers and Xie (2008).

The likelihood function for logit is

$$\ln L = \sum_{j \in S} w_j \ln F(\mathbf{x}_j \mathbf{b}) + \sum_{j \notin S} w_j \ln \{1 - F(\mathbf{x}_j \mathbf{b})\}$$

where  $S$  is the set of all observations  $j$ , such that  $y_j \neq 0$ ,  $F(z) = e^z/(1 + e^z)$ , and  $w_j$  denotes the optional weights. `lnL` is maximized as described in [R] **Maximize**.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] **\_robust**, particularly *Maximum likelihood estimators* and *Methods and formulas*. The scores are calculated as  $\mathbf{u}_j = \{1 - F(\mathbf{x}_j\mathbf{b})\}\mathbf{x}_j$  for the positive outcomes and  $-F(\mathbf{x}_j\mathbf{b})\mathbf{x}_j$  for the negative outcomes.

`logit` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] **Variance estimation**.

Joseph Berkson (1899–1982) was born in New York City and studied at the College of the City of New York, Columbia, and Johns Hopkins, earning both an MD and a doctorate in statistics. He then worked at Johns Hopkins before moving to the Mayo Clinic in 1931 as a biostatistician. Among many other contributions, his most influential one drew upon a long-sustained interest in the logistic function, especially his 1944 paper on bioassay, in which he introduced the term “logit”. Berkson was a frequent participant in controversy—sometimes humorous, sometimes bitter—on subjects such as the evidence for links between smoking and various diseases and the relative merits of probit and logit methods and of different calculation methods.

## Postestimation commands

The following postestimation commands are of special interest after `logit`:

| Command                           | Description                                                           |
|-----------------------------------|-----------------------------------------------------------------------|
| <code>estat classification</code> | report various summary statistics, including the classification table |
| <code>estat gof</code>            | Pearson or Hosmer–Lemeshow goodness-of-fit test                       |
| <code>lroc</code>                 | compute area under ROC curve and graph the curve                      |
| <code>lsens</code>                | graph sensitivity and specificity versus probability cutoff           |
| <code>lassogof</code>             | calculate goodness-of-fit predictions                                 |

These commands are not appropriate with `svy` estimation results.

The following standard postestimation commands are also available:

| Command                      | Description                                                                                                                             |
|------------------------------|-----------------------------------------------------------------------------------------------------------------------------------------|
| <code>contrast</code>        | contrasts and ANOVA-style joint tests of parameters                                                                                     |
| <code>estat ic</code>        | Akaike’s, consistent Akaike’s, corrected Akaike’s, and Schwarz’s Bayesian information criteria (AIC, CAIC, AICc, and BIC, respectively) |
| <code>estat summarize</code> | summary statistics for the estimation sample                                                                                            |
| <code>estat vce</code>       | variance–covariance matrix of the estimators (VCE)                                                                                      |
| <code>estat (svy)</code>     | postestimation statistics for survey data                                                                                               |
| <code>estimates</code>       | cataloging estimation results                                                                                                           |
| <code>etable</code>          | table of estimation results                                                                                                             |
| * <code>forecast</code>      | dynamic forecasts and simulations                                                                                                       |
| * <code>hausman</code>       | Hausman’s specification test                                                                                                            |
| <code>lincom</code>          | point estimates, standard errors, testing, and inference for linear combinations of parameters                                          |
| <code>linktest</code>        | link test for model specification                                                                                                       |
| * <code>lrtest</code>        | likelihood-ratio test                                                                                                                   |
| <code>margins</code>         | marginal means, predictive margins, marginal effects, and average marginal effects                                                      |
| <code>marginsplot</code>     | graph the results from <code>margins</code> (profile plots, interaction plots, etc.)                                                    |
| <code>nlcom</code>           | point estimates, standard errors, testing, and inference for nonlinear combinations of parameters                                       |
| <code>predict</code>         | probabilities, influence statistics, residuals, etc.                                                                                    |
| <code>predictnl</code>       | point estimates, standard errors, testing, and inference for generalized predictions                                                    |
| <code>pwcompare</code>       | pairwise comparisons of parameters                                                                                                      |
| <code>suest</code>           | seemingly unrelated estimation                                                                                                          |
| <code>test</code>            | Wald tests of simple and composite linear hypotheses                                                                                    |
| <code>testnl</code>          | Wald tests of nonlinear hypotheses                                                                                                      |

\*forecast, hausman, and lrtest are not appropriate with svy estimation results. forecast is also not appropriate with mi estimation results.

## predict

### Description for predict

predict creates a new variable containing predictions such as probabilities, linear predictions, standard errors, influence statistics, deviance residuals, leverages, sequential numbers, Pearson residuals, and the equation-level score.

### Menu for predict

Statistics > Postestimation

### Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset rules asif]
```

| <i>statistic</i> | Description |
|------------------|-------------|
|------------------|-------------|

Main

|                          |                                                                               |
|--------------------------|-------------------------------------------------------------------------------|
| <code>pr</code>          | probability of a positive outcome; the default                                |
| <code>xb</code>          | linear prediction                                                             |
| <code>stdp</code>        | standard error of the prediction                                              |
| * <code>dbeta</code>     | Pregibon (1981) $\Delta \hat{\beta}$ influence statistic                      |
| * <code>deviance</code>  | deviance residual                                                             |
| * <code>dx2</code>       | Hosmer, Lemeshow, and Sturdivant (2013) $\Delta \chi^2$ influence statistic   |
| * <code>ddeviance</code> | Hosmer, Lemeshow, and Sturdivant (2013) $\Delta D$ influence statistic        |
| * <code>hat</code>       | Pregibon (1981) leverage                                                      |
| * <code>number</code>    | sequential number of the covariate pattern                                    |
| * <code>residuals</code> | Pearson residuals; adjusted for number sharing covariate pattern              |
| * <code>rstandard</code> | standardized Pearson residuals; adjusted for number sharing covariate pattern |
| <code>score</code>       | first derivative of the log likelihood with respect to $\mathbf{x}_j\beta$    |

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

`pr`, `xb`, `stdp`, and `score` are the only options allowed with svy estimation results.

### Options for predict

Main

`pr`, the default, calculates the probability of a positive outcome.

`xb` calculates the linear prediction.

`stdp` calculates the standard error of the linear prediction.

`dbeta` calculates the Pregibon (1981)  $\Delta\hat{\beta}$  influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation along with all others that share the same covariate pattern. In Hosmer, Lemeshow, and Sturdivant (2013, 154–155) jargon, this statistic is  $M$ -asymptotic; that is, it is adjusted for the number of observations that share the same covariate pattern.

`deviance` calculates the deviance residual.

`dx2` calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191)  $\Delta\chi^2$  influence statistic, reflecting the decrease in the Pearson  $\chi^2$  that is due to deletion of the observation and all others that share the same covariate pattern.

`ddeviance` calculates the Hosmer, Lemeshow, and Sturdivant (2013, 191)  $\Delta D$  influence statistic, which is the change in the deviance residual that is due to deletion of the observation and all others that share the same covariate pattern.

`hat` calculates the Pregibon (1981) leverage or the diagonal elements of the hat matrix adjusted for the number of observations that share the same covariate pattern.

`number` numbers the covariate patterns—observations with the same covariate pattern have the same number. Observations not used in estimation have `number` set to missing. The first covariate pattern is numbered 1, the second 2, and so on.

`residuals` calculates the Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 155) and adjusted for the number of observations that share the same covariate pattern.

`rstandard` calculates the standardized Pearson residual as given by Hosmer, Lemeshow, and Sturdivant (2013, 191) and adjusted for the number of observations that share the same covariate pattern.

`score` calculates the equation-level score,  $\partial \ln L / \partial (\mathbf{x}_j \boldsymbol{\beta})$ .

---

#### Options

`nooffset` is relevant only if you specified `offset(varname)` for `logit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as  $\mathbf{x}_j \mathbf{b}$  rather than as  $\mathbf{x}_j \mathbf{b} + \text{offset}_j$ .

`rules` requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations.

`asif` requests that Stata ignore the rules and exclusion criteria and calculate predictions for all observations possible by using the estimated parameter from the model.

# margins

## Description for margins

margins estimates margins of response for probabilities and linear predictions.

## Menu for margins

Statistics > Postestimation

## Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]
```

| <i>statistic</i>       | Description                                    |
|------------------------|------------------------------------------------|
| <code>pr</code>        | probability of a positive outcome; the default |
| <code>xb</code>        | linear prediction                              |
| <code>stdp</code>      | not allowed with margins                       |
| <code>dbeta</code>     | not allowed with margins                       |
| <code>deviance</code>  | not allowed with margins                       |
| <code>dx2</code>       | not allowed with margins                       |
| <code>ddeviance</code> | not allowed with margins                       |
| <code>hat</code>       | not allowed with margins                       |
| <code>number</code>    | not allowed with margins                       |
| <code>residuals</code> | not allowed with margins                       |
| <code>rstandard</code> | not allowed with margins                       |
| <code>score</code>     | not allowed with margins                       |

Statistics not allowed with margins are functions of stochastic quantities other than  $e(b)$ .

For the full syntax, see [R] [margins](#).

## Remarks and examples

Once you have fit a logit model, you can obtain the predicted probabilities by using the `predict` command for both the estimation sample and other samples; see [U] [20 Estimation and postestimation commands](#) and [R] [predict](#). Here we will make only a few more comments.

`predict` without arguments calculates the predicted probability of a positive outcome, that is,  $\Pr(y_j = 1) = F(\mathbf{x}_j\mathbf{b})$ . With the `xb` option, `predict` calculates the linear combination  $\mathbf{x}_j\mathbf{b}$ , where  $\mathbf{x}_j$  are the independent variables in the  $j$ th observation and  $\mathbf{b}$  is the estimated parameter vector. This is sometimes known as the index function because the cumulative distribution function indexed at this value is the probability of a positive outcome.

In both cases, Stata remembers any rules used to identify the model and calculates missing for excluded observations, unless `rules` or `asif` is specified. For information about the other statistics available after `predict`, see [R] [logistic postestimation](#).

## ► Example 1: Predicted probabilities

In [example 2](#) of [\[R\] logit](#), we fit the logit model `logit foreign b3.repair`. To obtain predicted probabilities, type

```
. use https://www.stata-press.com/data/r19/repair
(1978 automobile data)
. logit foreign b3.repair
note: 1.repair != 0 predicts failure perfectly
 1.repair omitted and 10 obs not used
(output omitted)
. predict p
(option pr assumed; Pr(foreign))
(10 missing values generated)
. summarize foreign p
```

| Variable | Obs | Mean     | Std. dev. | Min | Max |
|----------|-----|----------|-----------|-----|-----|
| foreign  | 58  | .2068966 | .4086186  | 0   | 1   |
| p        | 48  | .25      | .1956984  | .1  | .5  |

Stata remembers any rules used to identify the model and sets predictions to missing for any excluded observations. `logit` omitted the variable `1.repair` from our model and excluded 10 observations. Thus when we typed `predict p`, those same 10 observations were again excluded, and their predictions were set to missing.

`predict's` `rules` option uses the rules in the prediction. During estimation, we were told “`1.repair != 0` predicts failure perfectly”, so the rule is that when `1.repair` is not zero, we should predict 0 probability of success or a positive outcome:

```
. predict p2, rules
(option pr assumed; Pr(foreign))
. summarize foreign p p2
```

| Variable | Obs | Mean     | Std. dev. | Min | Max |
|----------|-----|----------|-----------|-----|-----|
| foreign  | 58  | .2068966 | .4086186  | 0   | 1   |
| p        | 48  | .25      | .1956984  | .1  | .5  |
| p2       | 58  | .2068966 | .2016268  | 0   | .5  |

`predict's` `asif` option ignores the rules and exclusion criteria and calculates predictions for all observations possible by using the estimated parameters from the model:

```
. predict p3, asif
(option pr assumed; Pr(foreign))
. summarize foreign p p2 p3
```

| Variable | Obs | Mean     | Std. dev. | Min | Max |
|----------|-----|----------|-----------|-----|-----|
| foreign  | 58  | .2068966 | .4086186  | 0   | 1   |
| p        | 48  | .25      | .1956984  | .1  | .5  |
| p2       | 58  | .2068966 | .2016268  | 0   | .5  |
| p3       | 58  | .2931035 | .2016268  | .1  | .5  |

Which is right? What predict does by default is the most conservative approach. If many observations had been excluded because of a simple rule, we could be reasonably certain that the rules prediction is correct. The `asif` prediction is correct only if the exclusion is a fluke, and we would be willing to exclude the variable from the analysis anyway. Then, however, we would refit the model to include the excluded observations.

## ▷ Example 2: Predictive margins

We can use the command `margins, contrast` after `logit` to make comparisons on the probability scale. Let's fit a model predicting low birthweight from characteristics of the mother:

```
. use https://www.stata-press.com/data/r19/lbw, clear
(Hosmer & Lemeshow data)
. logit low age i.race i.smoke ptl i.ht i.ui

Iteration 0: Log likelihood = -117.336
Iteration 1: Log likelihood = -103.81846
Iteration 2: Log likelihood = -103.40486
Iteration 3: Log likelihood = -103.40384
Iteration 4: Log likelihood = -103.40384

Logistic regression Number of obs = 189
 LR chi2(7) = 27.86
 Prob > chi2 = 0.0002
 Pseudo R2 = 0.1187

Log likelihood = -103.40384
```

| low    | Coefficient | Std. err. | z     | P> z  | [95% conf. interval] |          |
|--------|-------------|-----------|-------|-------|----------------------|----------|
| age    | -.0403293   | .0357127  | -1.13 | 0.259 | -.1103249            | .0296663 |
| race   |             |           |       |       |                      |          |
| Black  | 1.009436    | .5025122  | 2.01  | 0.045 | .0245302             | 1.994342 |
| Other  | 1.001908    | .4248342  | 2.36  | 0.018 | .1692485             | 1.834568 |
| smoke  |             |           |       |       |                      |          |
| Smoker | .9631876    | .3904357  | 2.47  | 0.014 | .1979477             | 1.728427 |
| ptl    | .6288678    | .3399067  | 1.85  | 0.064 | -.0373371            | 1.295073 |
| i.ht   | 1.358142    | .6289555  | 2.16  | 0.031 | .125412              | 2.590872 |
| i.ui   | .8001832    | .4572306  | 1.75  | 0.080 | -.0959724            | 1.696339 |
| _cons  | -1.184127   | .9187461  | -1.29 | 0.197 | -2.984837            | .6165818 |

The coefficients are log odds-ratios: conditional on the other predictors, smoking during pregnancy is associated with an increase of 0.96 in the log odds of low birthweight. The model is linear in the log odds-scale, so the estimate of 0.96 has the same interpretation, whatever the values of the other predictors might be. We could convert 0.96 to an odds ratio by replaying the results with `logit, or`.

But what if we want to talk about the probability of low birthweight, and not the odds? Then we will need the command `margins, contrast`. We will use the `r.` contrast operator to compare each level of smoke with a reference level. (smoke has only two levels, so there will be only one comparison: a comparison of smokers with nonsmokers.)

```
. margins r.smoke, contrast
Contrasts of predictive margins Number of obs = 189
Model VCE: OIM
Expression: Pr(low), predict()
```

|       | df | chi2 | P>chi2 |  |
|-------|----|------|--------|--|
| smoke | 1  | 6.32 | 0.0119 |  |

|                                | Delta-method |           |                      |          |
|--------------------------------|--------------|-----------|----------------------|----------|
|                                | Contrast     | std. err. | [95% conf. interval] |          |
| smoke<br>(Smoker vs Nonsmoker) | .1832779     | .0728814  | .0404329             | .3261229 |

We see that maternal smoking is associated with an 18.3% increase in the probability of low birthweight. (We received a contrast in the probability scale because predicted probabilities are the default when `margins` is used after `logit`.)

The contrast of 18.3% is a difference of margins that are computed by averaging over the predictions for observations in the estimation sample. If the values of the other predictors were different, the contrast for smoke would be different, too. Let's estimate the contrast for 25-year-old mothers:

```
. margins r.smoke, contrast at(age=25)
Contrasts of predictive margins Number of obs = 189
Model VCE: OIM
Expression: Pr(low), predict()
At: age = 25
```

|       | df | chi2 | P>chi2 |  |
|-------|----|------|--------|--|
| smoke | 1  | 6.19 | 0.0129 |  |

|                                | Delta-method |           |                      |          |
|--------------------------------|--------------|-----------|----------------------|----------|
|                                | Contrast     | std. err. | [95% conf. interval] |          |
| smoke<br>(Smoker vs Nonsmoker) | .1808089     | .0726777  | .0383632             | .3232547 |

Specifying a maternal age of 25 changed the contrast to 18.1%. Our contrast of probabilities changed because the `logit` model is nonlinear in the probability scale. A contrast of log odds would not have changed.

## Methods and formulas

See *Methods and formulas* in [R] **logistic postestimation** for details on predictions. For all other postestimation commands, see *Methods and formulas* in the entries for the corresponding commands.

## loneway — Large one-way ANOVA, random effects, and reliability

[Description](#)

[Options](#)

[Acknowledgment](#)

[Quick start](#)

[Remarks and examples](#)

[References](#)

[Menu](#)

[Stored results](#)

[Also see](#)

[Syntax](#)

[Methods and formulas](#)

### Description

loneway fits one-way analysis-of-variance (ANOVA) models. loneway relaxes the restriction imposed by [oneway](#) that factors must have fewer than 376 levels. The command additionally reports the intraclass correlation, its standard error, and confidence interval; the estimated reliability of the group-averaged mean; the standard deviation of the group effect; and the standard deviation of the within-group effect.

### Quick start

One-way ANOVA model of  $y$  for factor  $a$

```
loneway y a
```

Report an exact 95% confidence interval for the intraclass correlation

```
loneway y a, exact
```

Same as above, but report a 90% confidence interval

```
loneway y a, exact level(90)
```

### Menu

Statistics > Linear models and related > ANOVA/MANOVA > Large one-way ANOVA

## Syntax

```
loneway response_var group_var [if] [in] [weight] [, options]
```

| options               | Description                                                       |
|-----------------------|-------------------------------------------------------------------|
| Main                  |                                                                   |
| <code>mean</code>     | expected value of $F$ distribution; default is 1                  |
| <code>median</code>   | median of $F$ distribution; default is 1                          |
| <code>exact</code>    | exact confidence intervals (groups must be equal with no weights) |
| <code>level(#)</code> | set confidence level; default is level(95)                        |

`by` and `collect` are allowed; see [\[U\] 11.1.10 Prefix commands](#).

`aweight`s are allowed; see [\[U\] 11.1.6 weight](#).

## Options

Main

`mean` specifies that the expected value of the  $F_{k-1, N-k}$  distribution be used as the reference point  $F_m$  in the estimation of  $\rho$  instead of the default value of 1.

`median` specifies that the median of the  $F_{k-1, N-k}$  distribution be used as the reference point  $F_m$  in the estimation of  $\rho$  instead of the default value of 1.

`exact` requests that exact confidence intervals be computed, as opposed to the default asymptotic confidence intervals. This option is allowed only if the groups are equal in size and weights are not used.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals of the coefficients. The default is level(95) or as set by `set level`; see [\[U\] 20.8 Specifying the width of confidence intervals](#).

## Remarks and examples

`loneway` and `oneway` both fit ANOVA models, but `loneway` presents different ancillary statistics from `oneway`:

| Feature                                    | oneway | loneway |
|--------------------------------------------|--------|---------|
| Fit one-way model                          | x      | x       |
| on 375 or fewer levels                     | x      | x       |
| on more than 375 levels                    |        | x       |
| Bartlett's test for equal variance         | x      |         |
| Multiple-comparison tests                  | x      |         |
| Intraclass correlation and SE              |        | x       |
| Intraclass correlation confidence interval |        | x       |
| Est. reliability of group-averaged mean    |        | x       |
| Est. SD of group effect                    |        | x       |
| Est. SD within group                       |        | x       |

Remarks are presented under the following headings:

*The one-way ANOVA model*  
 $R^2$   
*The random-effects ANOVA model*  
*Intraclass correlation*  
*Estimated reliability of the group-averaged score*

## The one-way ANOVA model

### ▷ Example 1

loneway's output looks like that of oneway, except that loneway presents more information at the end. Using our automobile dataset, we have created a (numeric) variable called `manufacturer_grp` identifying the manufacturer of each car, and within each manufacturer we have retained a maximum of four models, selecting those with the lowest mpg. We can compute the intraclass correlation of mpg for all manufacturers with at least four models as follows:

```
. use https://www.stata-press.com/data/r19/auto7
(1978 automobile data)
. loneway mpg manufacturer_grp if nummake == 4
```

One-way analysis of variance for mpg: Mileage (mpg)

| Source                 | SS        | df | MS        | F    | Prob > F |
|------------------------|-----------|----|-----------|------|----------|
| Between manufacturer~p | 621.88889 | 8  | 77.736111 | 3.70 | 0.0049   |
| Within manufacturer~p  | 567.75    | 27 | 21.027778 |      |          |
| Total                  | 1189.6389 | 35 | 33.989683 |      |          |

Number of obs = 36  
R-squared = 0.5228

| Intraclass correlation | Asy. S.E. | [95% conf. interval] |         |
|------------------------|-----------|----------------------|---------|
| 0.40270                | 0.18770   | 0.03481              | 0.77060 |

Estimated SD of manufacturer~p effect 3.765247  
Estimated SD within manufacturer~p 4.585605  
Est. reliability of a manufacturer~p mean 0.72950  
(evaluated at n=4.00)

◀

In addition to the standard one-way ANOVA output, loneway produces the  $R^2$ , the estimated standard deviation of the group effect, the estimated standard deviation within group, the intragroup correlation, the estimated reliability of the group-averaged mean, and, for unweighted data, the asymptotic standard error and confidence interval for the intragroup correlation.

$R^2$

The  $R^2$  is, of course, simply the underlying  $R^2$  for a regression of `response_var` on the levels of `group_var`, or mpg on the various manufacturers here.

## The random-effects ANOVA model

loneway assumes that we observe a variable,  $y_{ij}$ , measured for  $n_i$  elements within  $k$  groups or classes such that

$$y_{ij} = \mu + \alpha_i + \epsilon_{ij}, \quad i = 1, 2, \dots, k, \quad j = 1, 2, \dots, n_i$$

and  $\alpha_i$  and  $\epsilon_{ij}$  are independent zero-mean random variables with variance  $\sigma_\alpha^2$  and  $\sigma_\epsilon^2$ , respectively. This is the random-effects ANOVA model, also known as the components-of-variance model, in which it is typically assumed that the  $y_{ij}$  are normally distributed.

The interpretation with respect to our example is that the observed value of our response variable, mpg, is created in two steps. First, the  $i$ th manufacturer is chosen, and a value,  $\alpha_i$ , is determined—the typical mpg for that manufacturer less the overall mpg  $\mu$ . Then a deviation,  $\epsilon_{ij}$ , is chosen for the  $j$ th model within this manufacturer. This is how much that particular automobile differs from the typical mpg value for models from this manufacturer.

For our sample of 36 car models, the estimated standard deviations are  $\sigma_\alpha = 3.8$  and  $\sigma_\epsilon = 4.6$ . Thus, a little more than half of the variation in mpg between cars is attributable to the car model, with the rest attributable to differences between manufacturers. These standard deviations differ from those that would be produced by a (standard) fixed-effects regression in that the regression would require the sum within each manufacturer of the  $\epsilon_{ij}$ ,  $\epsilon_i$ , for the  $i$ th manufacturer, to be zero, whereas these estimates merely impose the constraint that the sum is *expected* to be zero.

## Intraclass correlation

There are various estimators of the intraclass correlation, such as the pairwise estimator, which is defined as the Pearson product-moment correlation computed over all possible pairs of observations that can be constructed within groups. For a discussion of various estimators, see [Donner \(1986\)](#). loneway computes what is termed the analysis of variance, or ANOVA, estimator. This intraclass correlation is the theoretical upper bound on the variation in *response\_var* that is explainable by *group\_var*, of which  $R^2$  is an overestimate because of the serendipity of fitting. This correlation is comparable to an  $R^2$ —you do not have to square it.

In our example, the intra-manu correlation, the correlation of mpg within manufacturer, is 0.40. Because *aweights* were not used and the default correlation was computed (that is, the mean and median options were not specified), loneway also provided the asymptotic confidence interval and standard error of the intraclass correlation estimate.

## Estimated reliability of the group-averaged score

The estimated reliability of the group-averaged score or mean has an interpretation similar to that of the intragroup correlation; it is a comparable number if we average *response\_var* by *group\_var*, or mpg by manu in our example. It is the theoretical upper bound of a regression of manufacturer-averaged mpg on characteristics of manufacturers. Why would we want to collapse our 36-observation dataset into a 9-observation dataset of manufacturer averages? Because the 36 observations might be a mirage. When General Motors builds cars, do they sometimes put a Pontiac label and sometimes a Chevrolet label on them, so that it appears in our data as if we have two cars when we really have only one, replicated? If that were the case, and if it were the case for many other manufacturers, then we would be forced to admit that we do not have data on 36 cars; we instead have data on nine manufacturer-averaged characteristics.

## Stored results

loneway stores the following in `r()`:

Scalars

|                     |                               |                       |                                     |
|---------------------|-------------------------------|-----------------------|-------------------------------------|
| <code>r(N)</code>   | number of observations        | <code>r(rho_t)</code> | estimated reliability               |
| <code>r(rho)</code> | intraclass correlation        | <code>r(se)</code>    | asypm. SE of intraclass correlation |
| <code>r(lb)</code>  | lower bound of 95% CI for rho | <code>r(sd_w)</code>  | estimated SD within group           |
| <code>r(ub)</code>  | upper bound of 95% CI for rho | <code>r(sd_b)</code>  | estimated SD of group effect        |

## Methods and formulas

The mean squares in the loneway's ANOVA table are computed as

$$MS_{\alpha} = \sum_i w_i (\bar{y}_i - \bar{y}_{..})^2 / (k - 1)$$

and

$$MS_{\epsilon} = \sum_i \sum_j w_{ij} (y_{ij} - \bar{y}_i)^2 / (N - k)$$

in which

$$w_i = \sum_j w_{ij} \quad w_{..} = \sum_i w_i \quad \bar{y}_i = \sum_j w_{ij} y_{ij} / w_i \quad \text{and} \quad \bar{y}_{..} = \sum_i w_i \bar{y}_i / w_{..}$$

The corresponding expected values of these mean squares are

$$E(MS_{\alpha}) = \sigma_{\epsilon}^2 + g\sigma_{\alpha}^2 \quad \text{and} \quad E(MS_{\epsilon}) = \sigma_{\epsilon}^2$$

in which

$$g = \frac{w_{..} - \sum_i w_i^2 / w_{..}}{k - 1}$$

In the unweighted case, we get

$$g = \frac{N - \sum_i n_i^2 / N}{k - 1}$$

As expected,  $g = m$  for the case of no weights and equal group sizes in the data, that is,  $n_i = m$  for all  $i$ . Replacing the expected values with the observed values and solving yields the ANOVA estimates of  $\sigma_{\alpha}^2$  and  $\sigma_{\epsilon}^2$ . Substituting these into the definition of the intraclass correlation

$$\rho = \frac{\sigma_{\alpha}^2}{\sigma_{\alpha}^2 + \sigma_{\epsilon}^2}$$

yields the ANOVA estimator of the intraclass correlation:

$$\rho_A = \frac{F_{\text{obs}} - 1}{F_{\text{obs}} - 1 + g}$$

$F_{\text{obs}}$  is the observed value of the  $F$  statistic from the ANOVA table. For no weights and equal  $n_i$ ,  $\rho_A = \text{roh}$ , which is the intragroup correlation defined by [Kish \(1965\)](#). Two slightly different estimators are available through the `mean` and `median` options ([Gleason 1997](#)). If either of these options is specified, the estimate of  $\rho$  becomes

$$\rho = \frac{F_{\text{obs}} - F_m}{F_{\text{obs}} + (g - 1)F_m}$$

For the mean option,  $F_m = E(F_{k-1, N-K}) = (N - k)/(N - k - 2)$ , that is, the expected value of the ANOVA table's  $F$  statistic. For the median option,  $F_m$  is simply the median of the  $F$  statistic. Setting  $F_m$  to 1 gives  $\rho_A$ , so for large samples, these different point estimators are essentially the same. Also, because the intraclass correlation of the random-effects model is by definition nonnegative, for any of the three possible point estimators,  $\rho$  is truncated to zero if  $F_{\text{obs}}$  is less than  $F_m$ .

For no weighting, interval estimators for  $\rho_A$  are computed. If the groups are equal sized (all  $n_i$  equal) and the exact option is specified, the following exact (assuming that the  $y_{ij}$  are normally distributed)  $100(1 - \alpha)\%$  confidence interval is computed:

$$\left\{ \frac{F_{\text{obs}} - F_m F_u}{F_{\text{obs}} + (g - 1) F_m F_u}, \frac{F_{\text{obs}} - F_m F_l}{F_{\text{obs}} + (g - 1) F_m F_l} \right\}$$

with  $F_m = 1$ ,  $F_l = F_{\alpha/2, k-1, N-k}$ , and  $F_u = F_{1-\alpha/2, k-1, N-k}$ ,  $F_{\cdot, k-1, N-k}$  being the cumulative distribution function for the  $F$  distribution with  $k - 1$  and  $N - k$  degrees of freedom. If mean or median is specified,  $F_m$  is defined as above. If the groups are equal sized and exact is not specified, the following asymptotic  $100(1 - \alpha)\%$  confidence interval for  $\rho_A$  is computed,

$$\left[ \rho_A - z_{\alpha/2} \sqrt{V(\rho_A)}, \rho_A + z_{\alpha/2} \sqrt{V(\rho_A)} \right]$$

where  $z_{\alpha/2}$  is the  $100(1 - \alpha/2)$  percentile of the standard normal distribution and  $\sqrt{V(\rho_A)}$  is the asymptotic standard error of  $\rho$  defined below. This confidence interval is also available for unequal groups. It is not applicable and, therefore, not computed for the estimates of  $\rho$  provided by the mean and median options. Again, because the intraclass coefficient is nonnegative, if the lower bound is negative for either confidence interval, it is truncated to zero. As might be expected, the coverage probability of a truncated interval is higher than its nominal value.

The asymptotic standard error of  $\rho_A$ , assuming that the  $y_{ij}$  are normally distributed, is also computed when appropriate, namely, for unweighted data and when  $\rho_A$  is computed (neither the mean option nor the median option is specified):

$$V(\rho_A) = \frac{2(1 - \rho)^2}{g^2} (A + B + C)$$

with

$$A = \frac{\{1 + \rho(g - 1)\}^2}{N - k}$$

$$B = \frac{(1 - \rho)\{1 + \rho(2g - 1)\}}{k - 1}$$

$$C = \frac{\rho^2 \{ \sum n_i^2 - 2N^{-1} \sum n_i^3 + N^{-2} (\sum n_i^2)^2 \}}{(k - 1)^2}$$

and  $\rho_A$  is substituted for  $\rho$  (Donner 1986).

The estimated reliability of the group-averaged score, known as the Spearman–Brown prediction formula in the psychometric literature (Winer, Brown, and Michels 1991, 1014), is

$$\rho_t = \frac{t\rho}{1 + (t - 1)\rho}$$

for group size  $t$ . loneway computes  $\rho_t$  for  $t = g$ .

The estimated standard deviation of the group effect is  $\sigma_\alpha = \sqrt{(\text{MS}_\alpha - \text{MS}_\epsilon)/g}$ . This deviation comes from the assumption that an observation is derived by adding a group effect to a within-group effect.

The estimated standard deviation within group is the square root of the mean square due to error, or  $\sqrt{\text{MS}_\epsilon}$ .

## Acknowledgment

We thank John Gleason (retired) of Syracuse University for his contributions to improving loneway.

## Description

`lowess` carries out a locally weighted regression of *yvar* on *xvar*, displays the graph, and optionally saves the smoothed variable.

Warning: `lowess` is computationally intensive and may therefore take a long time to run on a slow computer. Lowess calculations on 1,000 observations, for instance, require performing 1,000 regressions.

## Quick start

Locally weighted regression of *y1* on *x*

```
lowess y1 x
```

Same as above, but with a bandwidth of 0.4

```
lowess y1 x, bwidth(.4)
```

With running-mean smoothing

```
lowess y1 x, mean
```

Without the tricube weighting function

```
lowess y1 x, noweight
```

Generate a new variable *v* containing the smoothed values of *y1*

```
lowess y1 x, generate(v)
```

Adjust the mean of the smoothed values to equal the mean of the unsmoothed values

```
lowess y1 x, adjust
```

Lowess smoothing of categorical variable *y2* on *x* in terms of the log of the odds ratio

```
lowess y2 x, logit
```

## Menu

Statistics > Nonparametric analysis > Lowess smoothing

## Syntax

```
lowess yvar xvar [if] [in] [, options]
```

## Options

### Main

`mean` specifies running-mean smoothing; the default is running-line least-squares smoothing.

`nweight` prevents the use of Cleveland's (1979) tricube weighting function; the default is to use the weighting function.

`bwidth(#)` specifies the bandwidth. Centered subsets of `bwidth() × N` observations are used for calculating smoothed values for each point in the data except for the end points, where smaller, uncentered subsets are used. The greater the `bwidth()`, the greater the smoothing. The default is 0.8.

`logit` transforms the smoothed *yvar* into logits. Predicted values less than 0.0001 or greater than 0.9999 are set to  $1/N$  and  $1 - 1/N$ , respectively, before taking logits.

`adjust` adjusts the mean of the smoothed *yvar* to equal the mean of *yvar* by multiplying by an appropriate factor. This option is useful when smoothing binary (0/1) data.

`nograph` suppresses displaying the graph.

`generate(newvar)` creates *newvar* containing the smoothed values of *yvar*.

## Plot

*marker\_options* affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] *marker\_options*.

*marker\_label\_options* specify if and how the markers are to be labeled; see [G-3] *marker\_label\_options*.

## Smoothed line

*lineopts* (*cline\_options*) affects the rendition of the lowess-smoothed line; see [G-3] *cline\_options*.

## Add plots

*addplot* (*plot*) provides a way to add other plots to the generated graph; see [G-3] *addplot\_option*.

## Y axis, X axis, Titles, Legend, Overall, By

*twoway\_options* are any of the options documented in [G-3] *twoway\_options*. These include options for titling the graph (see [G-3] *title\_options*), options for saving the graph to disk (see [G-3] *saving\_option*), and the *by*() option (see [G-3] *by\_option*).

## Remarks and examples

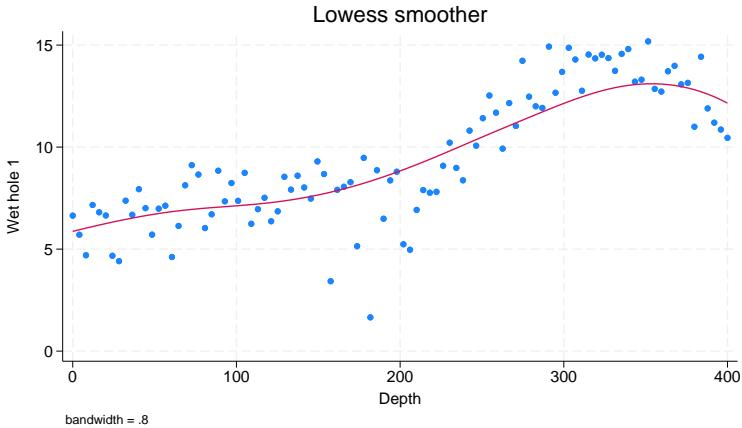

By default, *lowess* provides locally weighted scatterplot smoothing. The basic idea is to create a new variable (*newvar*) that, for each *yvar*  $y_i$ , contains the corresponding smoothed value. The smoothed values are obtained by running a regression of *yvar* on *xvar* by using only the data  $(x_i, y_i)$  and a few of the data near this point. In *lowess*, the regression is weighted so that the central point  $(x_i, y_i)$  gets the highest weight and points that are farther away (based on the distance  $|x_j - x_i|$ ) receive less weight. The estimated regression line is then used to predict the smoothed value  $\hat{y}_i$  for  $y_i$  only. The procedure is repeated to obtain the remaining smoothed values, which means that a separate weighted regression is performed for every point in the data.

Lowess is a desirable smoother because of its locality—it tends to follow the data. Polynomial smoothing methods, for instance, are global in that what happens on the extreme left of a scatterplot can affect the fitted values on the extreme right.

## ► Example 1

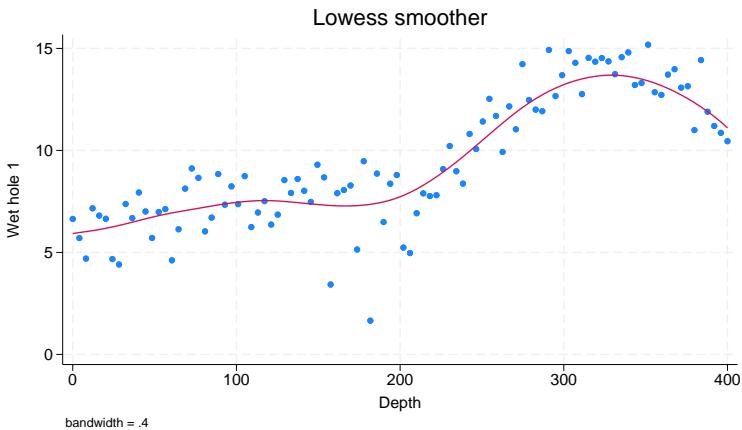

The amount of smoothing is affected by `bwidth(#)`. You are warned to experiment with different values. For instance,

```
. use https://www.stata-press.com/data/r19/lowess1
(Example data for lowess)
. lowess h1 depth
```

Now compare that with

```
. lowess h1 depth, bwidth(.4)
```

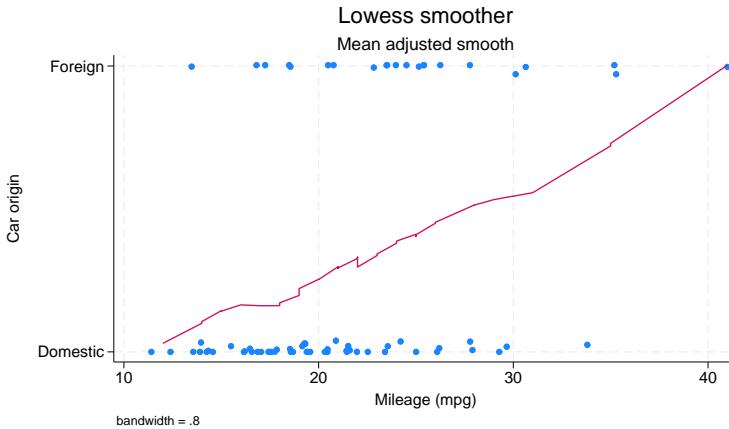

In the first case, the default bandwidth of 0.8 is used, meaning that 80% of the data are used in smoothing each point. In the second case, we explicitly specified a bandwidth of 0.4. Smaller bandwidths follow the original data more closely.

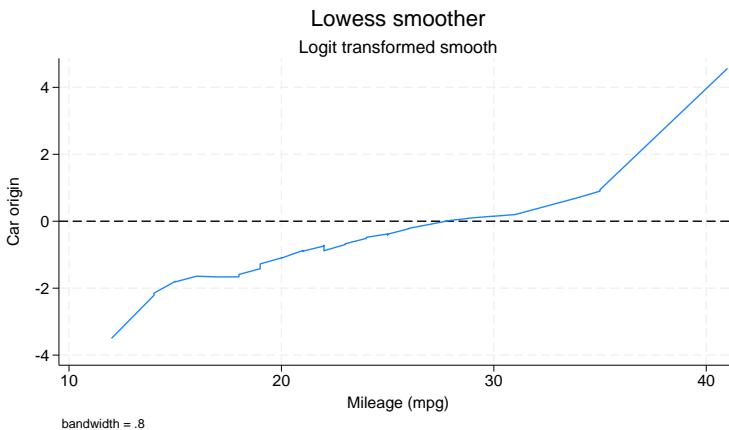

## ► Example 2

Two `lowess` options are especially useful with binary (0/1) data: `adjust` and `logit`. `adjust` adjusts the resulting curve (by multiplication) so that the mean of the smoothed values is equal to the mean of the unsmoothed values. `logit` specifies that the smoothed curve be in terms of the log of the odds ratio:

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. lowess foreign mpg, ylabel(0 "Domestic" 1 "Foreign") jitter(5) adjust
```

```
. lowess foreign mpg, logit yline(0)
```

With binary data, if you do not use the `logit` option, it is a good idea to specify `graph's jitter()` option; see [G-2] [graph twoway scatter](#). Because the underlying data (whether the car was manufactured outside the United States here) take on only two values, raw data points are more likely to be on top of each other, thus making it impossible to tell how many points there are. `graph's jitter()` option adds some noise to the data to shift the points around. This noise affects only the location of points on the graph, not the lowess curve.

When you specify the `logit` option, the display of the raw data is suppressed.

### □ Technical note

`lowess` can be used for more than just lowess smoothing. Lowess can be usefully thought of as a combination of two smoothing concepts: the use of predicted values from regression (rather than means) for imputing a smoothed value and the use of the tricube weighting function (rather than a constant weighting function). `lowess` allows you to combine these concepts freely. You can use line smoothing without weighting (specify `noweight`), mean smoothing with tricube weighting (specify `mean`), or mean smoothing without weighting (specify `mean` and `noweight`).

## Methods and formulas

Let  $y_i$  and  $x_i$  be the two variables, and assume that the data are ordered so that  $x_i \leq x_{i+1}$  for  $i = 1, \dots, N - 1$ . For each  $y_i$ , a smoothed value  $y_i^s$  is calculated.

The subset used in calculating  $y_i^s$  is indices  $i_- = \max(1, i - k)$  through  $i_+ = \min(i + k, N)$ , where  $k = \lfloor (N \times \text{bwidth} - 0.5)/2 \rfloor$ . The weights for each of the observations between  $j = i_-, \dots, i_+$  are either 1 (`noweight`) or the tricube (default),

$$w_j = \left\{ 1 - \left( \frac{|x_j - x_i|}{\Delta} \right)^3 \right\}^3$$

where  $\Delta = 1.0001 \max(x_{i_+} - x_i, x_i - x_{i_-})$ . The smoothed value  $y_i^s$  is then the (weighted) mean or the (weighted) regression prediction at  $x_i$ .

William Swain Cleveland (1943–) studied mathematics and statistics at Princeton and Yale. He worked for several years at Bell Labs in New Jersey and now teaches statistics and computer science at Purdue. He has made key contributions in many areas of statistics, including graphics and data visualization, time series, environmental applications, and analysis of internet traffic data.

## Acknowledgment

`lowess` is a modified version of a command originally written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

[Description](#)[Remarks and examples](#)[Quick start](#)[Stored results](#)[Menu](#)[Methods and formulas](#)[Syntax](#)[References](#)[Options](#)[Also see](#)

## Description

`lpoly` performs a kernel-weighted local polynomial regression of  $yvar$  on  $xvar$  and displays a graph of the smoothed values with (optional) confidence bands.

## Quick start

Kernel-weighted local polynomial regression of  $y$  on  $x$

```
lpoly y x
```

Same as above, but specify a bandwidth of 2

```
lpoly y x, bwidth(2)
```

Same as above, but specify a degree of 1

```
lpoly y x, bwidth(2) degree(1)
```

Same as above, but use the alternative Epanechnikov kernel

```
lpoly y x, bwidth(2) degree(1) kernel(epan2)
```

Same as above, but create a new variable for the smoothing grid  $g$  and smoothed values  $s$

```
lpoly y x, bwidth(2) degree(1) kernel(epan2) generate(g s)
```

With 95% confidence bands

```
lpoly y x, ci
```

Use `twoway` to graph multiple local polynomial fits

```
twoway scatter y x || ///
 lpoly y x, degree(1) kernel(epan2) || ///
 lpoly y x, degree(1) kernel(epan2) bwidth(1) || ///
 lpoly y x, degree(1) kernel(epan2) bwidth(7) ||
```

## Menu

Statistics > Nonparametric analysis > Local polynomial smoothing

## Syntax

```
lpoly yvar xvar [if] [in] [weight] [, options]
```

`collect` is allowed; see [U] 11.1.10 Prefix commands.

`fweights` and `aweights` are allowed; see [U] 11.1.6 weight.

## Options

### Main

`kernel` (*kernel*) specifies the kernel function for use in calculating the weighted local polynomial estimate. The default is `kernel(epanechnikov)`.

`width` (`#` | *varname*) specifies the half-width of the kernel—the width of the smoothing window around each point. If `width()` is not specified, a rule-of-thumb (ROT) bandwidth estimator is calculated and used. A local variable bandwidth may be specified in *varname*, in conjunction with an explicit smoothing grid using the `at()` option.

`degree` (`#`) specifies the degree of the polynomial to be used in the smoothing. The default is `degree(0)`, meaning local-mean smoothing.

`generate`( [*newvar<sub>x</sub>* ] *newvar<sub>s</sub>*) stores the smoothing grid in *newvar<sub>x</sub>* and the smoothed values in *newvar<sub>s</sub>*. If `at()` is not specified, then both *newvar<sub>x</sub>* and *newvar<sub>s</sub>* must be specified. Otherwise, only *newvar<sub>s</sub>* is to be specified.

`n` (`#`) specifies the number of points at which the smooth is to be calculated. The default is  $\min(N, 50)$ , where  $N$  is the number of observations.

`at` (*varname*) specifies a variable that contains the values at which the smooth should be calculated. By default, the smoothing is done on an equally spaced grid, but you can use `at()` to instead perform the smoothing at the observed  $x$ 's, for example. This option also allows you to more easily obtain smooths for different variables or different subsamples of a variable and then overlay the estimates for comparison.

`nograph` suppresses drawing the graph of the estimated smooth. This option is often used with the `generate()` option.

`nosm` suppresses superimposing a scatterplot of the observed data over the smooth. This option is useful when the number of resulting points would be so large as to clutter the graph.

## SE/CI

`ci` plots confidence bands, using the confidence level specified in `level()`.

`level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 [Specifying the width of confidence intervals](#).

`se(newvar)` stores the estimates of the standard errors in *newvar*. This option requires specifying `generate()` or `at()`.

`pwidth(#)` specifies the pilot bandwidth to be used for standard error computations. The default is chosen to be 1.5 times the value of the ROT bandwidth selector. If you specify `pwidth()` without specifying `se()` or `ci`, then the `ci` option is assumed.

`var(#|varname)` specifies an estimate of a constant residual variance or a variable containing estimates of the residual variances at each grid point required for standard error computation. By default, the residual variance at each smoothing point is estimated by the normalized weighted residual sum of squares obtained from locally fitting a polynomial of order  $p + 2$ , where  $p$  is the degree specified in `degree()`. `var(varname)` is allowed only if `at()` is specified. If you specify `var()` without specifying `se()` or `ci`, then the `ci` option is assumed.

## Scatterplot

`marker_options` affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] [marker\\_options](#).

`marker_label_options` specify if and how the markers are to be labeled; see [G-3] [marker\\_label\\_options](#).

## Smoothed line

`lineopts(cline_options)` affects the rendition of the smoothed line; see [G-3] [cline\\_options](#).

## CI plot

`ciopts(cline_options)` affects the rendition of the confidence bands; see [G-3] [cline\\_options](#).

## Add plots

`addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] [addplot\\_option](#).

## Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] [twoway\\_options](#), excluding `by()`. These include options for titling the graph (see [G-3] [title\\_options](#)) and for saving the graph to disk (see [G-3] [saving\\_option](#)).

## Remarks and examples

Remarks are presented under the following headings:

[Introduction](#)  
[Local polynomial smoothing](#)  
[Choice of a bandwidth](#)  
[Confidence bands](#)

## Introduction

The last 25 years or so has seen a significant outgrowth in the literature on scatterplot smoothing, otherwise known as univariate nonparametric regression. Of most appeal is the idea of making no assumptions about the functional form for the expected value of a response given a regressor, but instead allowing the data to “speak for themselves”. Various methods and estimators fall into the category of nonparametric regression, including local mean smoothing as described independently by [Nadaraya \(1964\)](#) and [Watson \(1964\)](#), the [Gasser and Müller \(1979\)](#) estimator, locally weighted scatterplot smoothing (LOWESS) as described by [Cleveland \(1979\)](#), wavelets (for example, [Donoho \[1995\]](#)), and splines ([Eubank 1999](#)), to name a few. Much of the vast literature focuses on automating the amount of smoothing to be performed and dealing with the bias/variance tradeoff inherent to this type of estimation. For example, for Nadaraya–Watson the amount of smoothing is controlled by choosing a *bandwidth*.

Smoothing via local polynomials is by no means a new idea but instead one that has been rediscovered in recent years in articles such as [Fan \(1992\)](#). A natural extension of the local mean smoothing of Nadaraya–Watson, local polynomial regression involves fitting the response to a polynomial form of the regressor via locally weighted least squares. Higher-order polynomials have better bias properties than the zero-degree local polynomials of the Nadaraya–Watson estimator; in general, higher-order polynomials do not require bias adjustment at the boundary of the regression space. For a definitive reference on local polynomial smoothing, see [Fan and Gijbels \(1996\)](#).

## Local polynomial smoothing

Consider a set of scatterplot data  $\{(x_1, y_1), \dots, (x_n, y_n)\}$  from the model

$$y_i = m(x_i) + \sigma(x_i)\epsilon_i \quad (1)$$

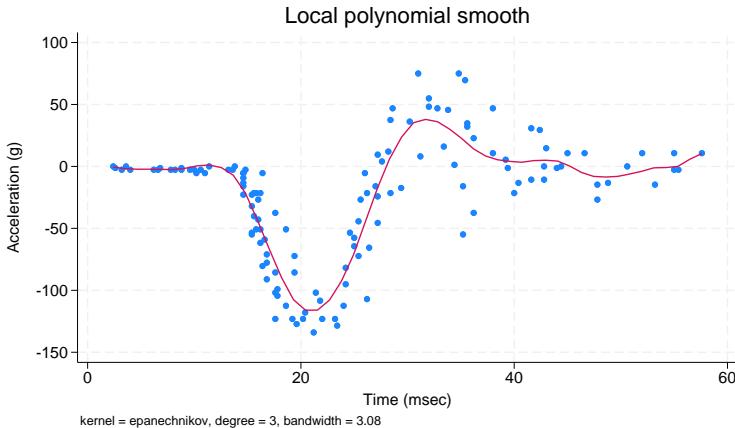

for some unknown mean and variance functions  $m(\cdot)$  and  $\sigma^2(\cdot)$ , and symmetric errors  $\epsilon_i$  with  $E(\epsilon_i) = 0$  and  $\text{Var}(\epsilon_i) = 1$ . The goal is to estimate  $m(x_0) = E[Y|X = x_0]$ , making no assumption about the functional form of  $m(\cdot)$ .

`lpoly` estimates  $m(x_0)$  as the constant term (intercept) of a regression, weighted by the kernel function specified in `kernel()`, of `yvar` on the polynomial terms  $(xvar - x_0), (xvar - x_0)^2, \dots, (xvar - x_0)^p$  for each smoothing point  $x_0$ . The degree of the polynomial,  $p$ , is specified in `degree()`, the amount of smoothing is controlled by the bandwidth specified in `width()`, and the chosen kernel function is specified in `kernel()`.

## ▷ Example 1

Consider the motorcycle data as examined (among other places) in [Fan and Gijbels \(1996\)](#). The data consist of 133 observations and measure the acceleration (accel measured in grams [g]) of a dummy's head during impact over time (time measured in milliseconds). For these data, we use `lpoly` to fit a local cubic polynomial with the default bandwidth (obtained using the ROT method) and the default Epanechnikov kernel.

```
. use https://www.stata-press.com/data/r19/motorcycle
(Motorcycle data from Fan & Gijbels (1996))
. lpoly accel time, degree(3)
```

## □ Technical note

`lpoly` allows specifying in `degree()` both odd and even orders of the polynomial to be used for the smoothing. However, the odd-order,  $2k + 1$ , polynomial approximations are preferable. They have an extra parameter compared with the even-order,  $2k$ , approximations, which leads to a significant bias reduction and there is no increase of variability associated with adding this extra parameter. Using an odd order when estimating the regression function is therefore usually sufficient. For a more thorough discussion, see [Fan and Gijbels \(1996\)](#).

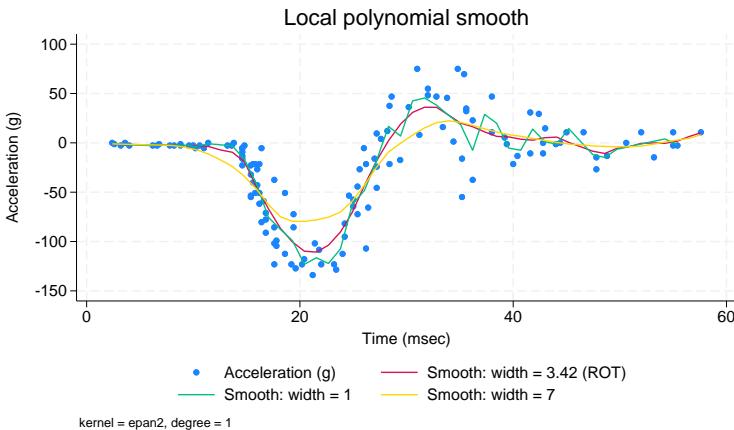

## Choice of a bandwidth

The choice of a bandwidth is crucial for many smoothing techniques, including local polynomial smoothing. In general, using a large bandwidth gives smooths with a large bias, whereas a small bandwidth may result in highly variable smoothed values. Various techniques exist for optimal bandwidth selection. By default, `lpoly` uses the ROT method to estimate the bandwidth used for the smoothing; see [Methods and formulas](#) for details.

### ► Example 2

Using the `motorcycle` data, we demonstrate how a local linear polynomial fit changes using different bandwidths.

```
. lpoly accel time, degree(1) kernel(epan2) bwidth(1)
> generate(at smooth1) nograph
. lpoly accel time, degree(1) kernel(epan2) bwidth(7) at(at)
> generate(smooth2) nograph
. label variable smooth1 "Smooth: width = 1"
. label variable smooth2 "Smooth: width = 7"
. lpoly accel time, degree(1) kernel(epan2) at(at) addplot(line smooth* at)
> legend(label(2 "Smooth: width = 3.42 (ROT)") cols(2) pos(6))
> note("kernel = epan2, degree = 1")
```

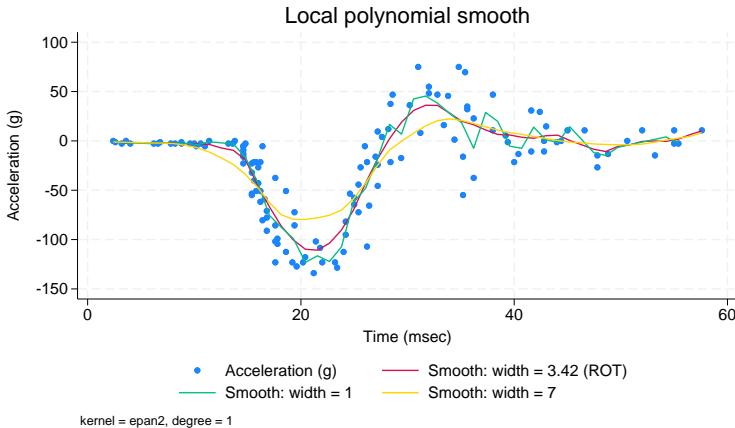

From this graph, we can see that the local linear polynomial fit with larger bandwidth (`width = 7`) corresponds to a smoother line but fails to fit the curvature of the scatterplot data. The smooth obtained using the width equal to one seems to fit most data points, but the corresponding line has several spikes indicating larger variability. The smooth obtained using the ROT bandwidth estimator seems to have a good tradeoff between the fit and variability in this example.

In the above, we also demonstrated how the `generate()` and `addplot()` options may be used to produce overlaid plots obtained from `lpoly` with different options. The `nograph` option saves time when you need to save only results with `generate()`.

However, to avoid generating variables manually, one can use `twoway lpoly` instead; see [G-2] [graph twoway lpoly](#) for more details.

```
. twoway scatter accel time ||
> lpoly accel time, degree(1) kernel(epan2) lpattern(solid) ||
> lpoly accel time, degree(1) kernel(epan2) bwidth(1) ||
> lpoly accel time, degree(1) kernel(epan2) bwidth(7) ||
> , legend(label(2 "Smooth: width = 3.42 (ROT)")
> label(3 "Smooth: width = 1")
> label(4 "Smooth: width = 7") cols(2) pos(6))
> title("Local polynomial smooth") note("kernel = epan2, degree = 1")
> xtitle("Time (msec)") ytitle("Acceleration (g)")
```

◀

The ROT estimate is commonly used as an initial guess for the amount of smoothing; this approach may be sufficient when the choice of a bandwidth is less important. In other cases, you can pick your own bandwidth.

When the shape of the regression function has a combination of peaked and flat regions, a variable bandwidth may be preferable over the constant bandwidth to allow for different degrees of smoothness in different regions. The `bwidth()` option allows you to specify the values of the local variable bandwidths as those stored in a variable in your data.

Similar issues with bias and variability arise when choosing a pilot bandwidth (the `pwidth()` option) used to compute standard errors of the local polynomial smoother. The default value is chosen to be  $1.5 \times \text{ROT}$ . For a review of methods for pilot bandwidth selection, see [Fan and Gijbels \(1996\)](#).

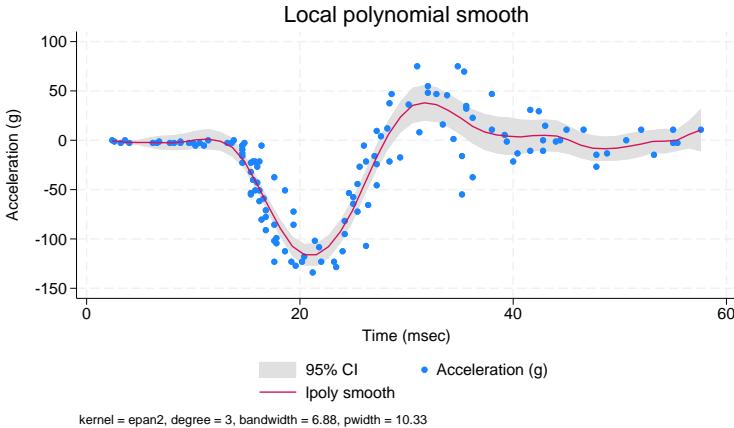

## Confidence bands

The established asymptotic normality of the local polynomial estimators under certain conditions allows the construction of approximate confidence bands. `lpoly` offers the `ci` option to plot these bands.

### ▷ Example 3

Let us plot the confidence bands for the local polynomial fit from [example 1](#).

```
. lpoly accel time, degree(3) kernel(epan2) ci legend(cols(2) pos(6))
```

You can obtain graphs with overlaid confidence bands by using `twoway lpolyci`; see [\[G-2\] graph twoway lpolyci](#) for examples.

Constructing the confidence intervals involves computing standard errors obtained by taking a square root of the estimate of the conditional variance of the local polynomial estimator at each grid point  $x_0$ . Estimating the conditional variance requires fitting a polynomial of a higher order locally by using a different bandwidth, the pilot bandwidth. The value of the pilot bandwidth may be supplied by using `pwidth()`. By default, the value of  $1.5 \times \text{ROT}$  is used. Also, estimates of the residual variance  $\sigma^2(x_0)$  at each grid point,  $x_0$ , are required to obtain the estimates of the conditional variances. These estimates may be supplied by using the `var()` option. By default, they are computed using the normalized weighted residual sum of squares from a local polynomial fit of a higher order. See [Methods and formulas](#) for details. The standard errors may be saved by using `se()`.

## Stored results

`lpoly` stores the following in `r()`:

### Scalars

|                        |                                  |                        |                         |

## Methods and formulas

Consider model (1), written in matrix notation,

$$\mathbf{y} = m(\mathbf{x}) + \epsilon$$

where  $\mathbf{y}$  and  $\mathbf{x}$  are the  $n \times 1$  vectors of scatterplot values,  $\epsilon$  is the  $n \times 1$  vector of errors with zero mean and covariance matrix  $\Sigma = \text{diag}\{\sigma(x_i)\}\mathbf{I}_n$ , and  $m(\cdot)$  and  $\sigma(\cdot)$  are some unknown functions. Define  $m(x_0) = E[Y|X = x_0]$  and  $\sigma^2(x_0) = \text{Var}[Y|X = x_0]$  to be the conditional mean and conditional variance of random variable  $Y$  (residual variance), respectively, for some realization  $x_0$  of random variable  $X$ .

The method of local polynomial smoothing is based on the approximation of  $m(x)$  locally by a  $p$ th order polynomial in  $(x - x_0)$  for some  $x$  in the neighborhood of  $x_0$ . For the scatterplot data  $\{(x_1, y_1), \dots, (x_n, y_n)\}$ , the  $p$ th-order local polynomial smooth  $\widehat{m}(x_0)$  is equal to  $\widehat{\beta}_0$ , an estimate of the intercept of the weighted linear regression,

$$\widehat{\beta} = (\mathbf{X}^T \mathbf{W} \mathbf{X})^{-1} \mathbf{X}^T \mathbf{W} \mathbf{y} \quad (2)$$

where  $\widehat{\beta} = (\widehat{\beta}_0, \widehat{\beta}_1, \dots, \widehat{\beta}_p)^T$  is the vector of estimated regression coefficients (with  $\{\widehat{\beta}_j = (j!)^{-1} \widehat{m}^{(j)}(x)|_{x=x_0}, j = 0, \dots, p\}$  also representing estimated coefficients from a corresponding Taylor expansion);  $\mathbf{X} = \{(x_i - x_0)^j\}_{i,j=1,0}^{n,p}$  is a design matrix; and  $\mathbf{W} = \text{diag}\{K_h(x_i - x_0)\}_{n \times n}$  is a weight matrix with weights  $K_h(\cdot)$  defined as  $K_h(x) = h^{-1}K(x/h)$ , with  $K(\cdot)$  being a kernel function and  $h$  defining a bandwidth. The kernels are defined in [Methods and formulas](#) of `[R] kdensity`.

The default bandwidth is obtained using the ROT method of bandwidth selection. The ROT bandwidth is the plugin estimator of the asymptotically optimal constant bandwidth. This is the bandwidth that minimizes the conditional weighted mean integrated squared error. The ROT plugin bandwidth selector for the smoothing bandwidth  $h$  is defined as follows; assuming constant residual variance  $\sigma^2(x_0) = \sigma^2$  and odd degree  $p$ :

$$\widehat{h} = C_{0,p}(K) \left[ \frac{\widehat{\sigma}^2 \int w_0(x) dx}{n \int \{\widehat{m}^{(p+1)}(x)\}^2 w_0(x) f(x) dx} \right]^{1/(2p+3)} \quad (3)$$

where  $C_{0,p}(K)$  is a constant, as defined in [Fan and Gijbels \(1996\)](#), that depends on the kernel function  $K(\cdot)$ , and the degree of a polynomial  $p$  and  $w_0$  is chosen to be an indicator function on the interval  $[\min_{\mathbf{x}} + 0.05 \times \text{range}_{\mathbf{x}}, \max_{\mathbf{x}} - 0.05 \times \text{range}_{\mathbf{x}}]$  with  $\min_{\mathbf{x}}$ ,  $\max_{\mathbf{x}}$ , and  $\text{range}_{\mathbf{x}}$  being, respectively, the minimum, maximum, and the range of  $\mathbf{x}$ . To obtain the estimates of a constant residual variance,  $\widehat{\sigma}^2$ , and  $(p + 1)$ th order derivative of  $m(x)$ , denoted as  $\widehat{m}^{(p+1)}(x)$ , a polynomial in  $\mathbf{x}$  of order  $(p + 3)$  is fit globally to  $\mathbf{y}$ .  $\widehat{\sigma}^2$  is estimated as a standardized residual sum of squares from this fit.

The expression for the asymptotically optimal constant bandwidth used in constructing the ROT bandwidth estimator is derived for the odd-order polynomial approximations. For even-order polynomial fits the expression would depend not only on  $m^{(p+1)}(x)$  but also on  $m^{(p+2)}(x)$  and the design density and its derivative,  $f(x)$  and  $f'(x)$ . Therefore, the ROT bandwidth selector would require estimation of these additional quantities. Instead, for an even-degree  $p$  of the local polynomial, `lpoly` uses the value of the ROT estimator (3) computed using degree  $p + 1$ . As such, for even degrees this is not a plugin estimator of the asymptotically optimal constant bandwidth.

The estimates of the conditional variance of local polynomial estimators are obtained using

$$\widehat{\text{Var}}\{\widehat{m}(x_0)|X = x_0\} = \widehat{\sigma}_m^2(x_0) = (\mathbf{X}^T\mathbf{W}\mathbf{X})^{-1}(\mathbf{X}^T\mathbf{W}^2\mathbf{X})(\mathbf{X}^T\mathbf{W}\mathbf{X})^{-1}\widehat{\sigma}^2(x_0) \quad (4)$$

where  $\widehat{\sigma}^2(x_0)$  is estimated by the normalized weighted residual sum of squares from the  $(p + 2)$ th order polynomial fit using pilot bandwidth  $h^*$ .

When the bias is negligible the normal-approximation method yields a  $(1 - \alpha) \times 100\%$  confidence interval for  $m(x_0)$ ,

$$\{\widehat{m}(x_0) - z_{(1-\alpha/2)}\widehat{\sigma}_m(x_0), \widehat{m}(x_0) + z_{(1-\alpha/2)}\widehat{\sigma}_m(x_0)\}$$

where  $z_{(1-\alpha/2)}$  is the  $(1 - \alpha/2)$ th quantile of the standard Gaussian distribution, and  $\widehat{m}(x_0)$  and  $\widehat{\sigma}_m(x_0)$  are as defined in (2) and (4), respectively.

### **Description**

`lroc` graphs the ROC curve and calculates the area under the curve.

`lroc` requires that the current estimation results be from `logistic`, `logit`, `probit`, or `ivprobit`; see [\[R\] logistic](#), [\[R\] logit](#), [\[R\] probit](#), or [\[R\] ivprobit](#).

### **Quick start**

Graph and compute area under ROC curve for current estimation results

```
lroc
```

Add “My Title” as title of graph

```
lroc, title(My Title)
```

Suppress graph

```
lroc, nograph
```

## Options

### Main

`all` requests that the statistic be computed for all observations in the data, ignoring any `if` or `in` restrictions specified by the estimation command.

`nograph` suppresses graphical output.

### Advanced

`beta(matname)` specifies a row vector containing model coefficients. The columns of the row vector must be labeled with the corresponding names of the independent variables in the data. The dependent variable *depvar* must be specified immediately after the command name. See [Models other than the last fitted model](#) later in this entry.

### Plot

`cline_options`, `marker_options`, and `marker_label_options` affect the rendition of the ROC curve—the plotted points connected by lines. These options affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] [cline\\_options](#), [G-3] [marker\\_options](#), and [G-3] [marker\\_label\\_options](#).

## Reference line

`rlopts` (*cline\_options*) affects the rendition of the reference line; see [G-3] *cline\_options*.

## Add plots

`addplot` (*plot*) provides a way to add other plots to the generated graph; see [G-3] *addplot\_option*.

## Y axis, X axis, Titles, Legend, Overall

*twoway\_options* are any of the options documented in [G-3] *twoway\_options*, excluding `by()`. These include options for titling the graph (see [G-3] *title\_options*) and for saving the graph to disk (see [G-3] *saving\_option*).

## Remarks and examples

Remarks are presented under the following headings:

*Introduction*

*Samples other than the estimation sample*

*Models other than the last fitted model*

### Introduction

Stata also has a suite of commands for performing both parametric and nonparametric receiver operating characteristic (ROC) analysis. See [R] *roc* for an overview of these commands.

`lroc` graphs the ROC curve—a graph of sensitivity versus one minus specificity as the cutoff  $c$  is varied—and calculates the area under it. Sensitivity is the fraction of observed positive-outcome cases that are correctly classified; specificity is the fraction of observed negative-outcome cases that are correctly classified. When the purpose of the analysis is classification, you must choose a cutoff.

The curve starts at  $(0, 0)$ , corresponding to  $c = 1$ , and continues to  $(1, 1)$ , corresponding to  $c = 0$ . A model with no predictive power would be a 45° line. The greater the predictive power, the more bowed the curve, and hence the area beneath the curve is often used as a measure of the predictive power. A model with no predictive power has area 0.5; a perfect model has area 1.

The ROC curve was first discussed in signal detection theory (Peterson, Birdsall, and Fox 1954) and then was quickly introduced into psychology (Tanner and Swets 1954). It has since been applied in other fields, particularly medicine (for instance, Metz [1978]). For a classic text on ROC techniques, see Green and Swets (1966).

`lsens` also plots sensitivity and specificity; see [R] *lsens*.

### ▶ Example 1

Hardin and Hilbe (2018) examine data from the National Canadian Registry of Cardiovascular Disease (FASTRAK), sponsored by Hoffman-La Roche Canada. They model death within 48 hours based on whether a patient suffers an anterior infarct (heart attack) rather than an inferior infarct using a logistic regression and evaluate the model using an ROC curve. We replicate their analysis here.

Both anterior and inferior refer to sites on the heart where damage occurs. The model is also adjusted for `hcabg`, whether the subject has had a cardiac bypass surgery (CABG); `age`, a four-category age-group indicator; and `killip`, a four-level risk indicator.

We load the data and then estimate the parameters of the logistic regression with `logistic`. Factor-variable notation is used for each predictor, because they are categorical; see [U] 11.4.3 *Factor variables*.

```
. use https://www.stata-press.com/data/r19/heart
(Heart attacks)
. logistic death i.site i.hcabg i.killip i.age
Logistic regression
Log likelihood = -636.62553
Number of obs = 4,483
LR chi2(8) = 211.37
Prob > chi2 = 0.0000
Pseudo R2 = 0.1424
```

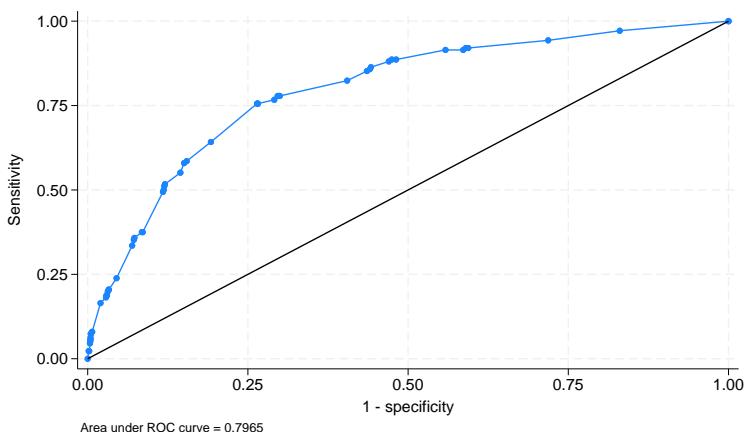

| death    | Odds ratio | Std. err. | z      | P> z  | [95% conf. interval] |          |
|----------|------------|-----------|--------|-------|----------------------|----------|
| site     |            |           |        |       |                      |          |
| Anterior | 1.901333   | .3185757  | 3.83   | 0.000 | 1.369103             | 2.640464 |
| 1.hcabg  | 2.105275   | .7430694  | 2.11   | 0.035 | 1.054076             | 4.204801 |
| killip   |            |           |        |       |                      |          |
| 2        | 2.251732   | .4064423  | 4.50   | 0.000 | 1.580786             | 3.207453 |
| 3        | 2.172105   | .584427   | 2.88   | 0.004 | 1.281907             | 3.680487 |
| 4        | 14.29137   | 5.087654  | 7.47   | 0.000 | 7.112964             | 28.71423 |
| age      |            |           |        |       |                      |          |
| 60-69    | 1.63726    | .5078582  | 1.59   | 0.112 | .8914261             | 3.007115 |
| 70-79    | 4.532029   | 1.206534  | 5.68   | 0.000 | 2.689568             | 7.636647 |
| >=80     | 8.893222   | 2.41752   | 8.04   | 0.000 | 5.219991             | 15.15125 |
| _cons    | .0063961   | .0016541  | -19.54 | 0.000 | .0038529             | .010618  |

Note: **\_cons** estimates baseline odds.

The odds ratios for a unit change in each covariate are reported by `logistic`. At fixed values of the other covariates, patients who enter Canadian hospitals with an anterior infarct have nearly twice the odds of death within 48 hours than those with an inferior infarct. Those who have had a previous CABG have approximately twice the risk of death of those who have not. Those with higher Killip risks and those who are older are also at greater risk of death.

We use `lroc` to draw the ROC curve for the model. The area under the curve of approximately 0.8 indicates acceptable discrimination for the model.

```
. lroc
Logistic model for death
Number of observations = 4483
Area under ROC curve = 0.7965
```

## Samples other than the estimation sample

`lroc` can be used with samples other than the estimation sample. By default, `lroc` remembers the estimation sample used with the last `logistic`, `logit`, `probit`, or `ivprobit` command. To override this, simply use an `if` or `in` restriction to select another set of observations, or specify the `all` option to force the command to use all the observations in the dataset.

See [example 3](#) in [\[R\] estat gof](#) for an example of using `lroc` with a sample other than the estimation sample.

## Models other than the last fitted model

By default, `lroc` uses the last model fit by `logistic`, `logit`, `probit`, or `ivprobit`. You may also directly specify the model to `lroc` by inputting a vector of coefficients with the `beta()` option and passing the name of the dependent variable `devar` to `lroc`.

### ▷ Example 2

Suppose that someone publishes the following logistic model of low birthweight:

$$\Pr(\text{low} = 1) = F(-0.02 \text{ age} - 0.01 \text{ lwt} + 1.3 \text{ black} + 1.1 \text{ smoke} + 0.5 \text{ pt1} + 1.8 \text{ ht} + 0.8 \text{ ui} + 0.5)$$

where  $F$  is the cumulative logistic distribution. These coefficients are not odds ratios; they are the equivalent of what `logit` produces.

We can see whether this model fits our data. First, we enter the coefficients as a row vector and label its columns with the names of the independent variables plus `_cons` for the constant (see [\[P\] matrix define](#) and [\[P\] matrix rownames](#)).

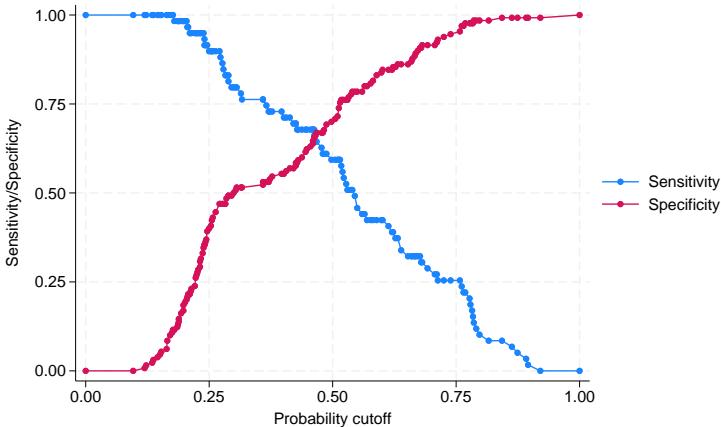

```
. use https://www.stata-press.com/data/r19/lbw3, clear
(Hosmer & Lemeshow data)
. matrix input b = (-.02, -.01, 1.3, 1.1, .5, 1.8, .8, .5)
. matrix colnames b = age lwt black smoke ptl ht ui _cons
```

Here we use `lroc` to examine the predictive ability of the model:

```
. lroc low, beta(b) nograph
Logistic model for low
Number of observations = 189
Area under ROC curve = 0.7275
```

The area under the curve indicates that this model does have some predictive power. We can obtain a graph of sensitivity and specificity as a function of the cutoff probability by typing

```
. lsens low, beta(b)
```

See [R] `lsens`.

## Stored results

`lroc` stores the following in `r()`:

Scalars

|                      |                          |
|----------------------|--------------------------|
| <code>r(N)</code>    | number of observations   |
| <code>r(area)</code> | area under the ROC curve |

## Methods and formulas

The ROC curve is a graph of *sensitivity* against  $(1 - \textit{specificity})$ . This is guaranteed to be a monotone nondecreasing function because the number of correctly predicted successes increases and the number of correctly predicted failures decreases as the classification cutoff  $c$  decreases.

The area under the ROC curve is the area on the bottom of this graph and is determined by integrating the curve. The vertices of the curve are determined by sorting the data according to the predicted index, and the integral is computed using the trapezoidal rule.

## Description

`lrtest` performs a likelihood-ratio test of the null hypothesis that the parameter vector of a statistical model satisfies some smooth constraint. To conduct the test, both the unrestricted and the restricted models must be fit using the maximum likelihood method (or some equivalent method), and the results of at least one must be stored using `estimates store`.

`lrtest` also supports composite models. In a composite model, we assume that the log likelihood and dimension (number of free parameters) of the full model are obtained as the sum of the log-likelihood values and dimensions of the constituting models.

## Quick start

Likelihood-ratio test that the coefficients for `x2` and `x3` are equal to 0

```
logit y x1 x2 x3
estimates store full
```

```
logit y x1 if e(sample)
estimates store restricted
```

```
lrtest full restricted
```

Display additional information, including AIC and BIC

```
lrtest full restricted, stats
```

Likelihood-ratio test that the coefficients for `x1` and `x3` are equal

```
constraint 1 x1=x3
logit y x1 x2 x3, constraints(1)
estimates store constrained
```

```
lrtest full constrained
```

Compare stored estimates `full` with the last model run

```
lrtest full
```

## Menu

Statistics > Postestimation

## Syntax

```
lrtest modelspec1 [modelspec2] [, options]
```

*modelspec*<sub>1</sub> and *modelspec*<sub>2</sub> specify the restricted and unrestricted model in any order. *modelspec*# is *name* | . | (*namelist*)

*name* is the name under which estimation results were stored using `estimates store` (see [R] [estimates store](#)), and “.” refers to the last estimation results, whether or not these were already stored. If *modelspec*<sub>2</sub> is not specified, the last estimation result is used; this is equivalent to specifying *modelspec*<sub>2</sub> as “.”.

If *namelist* is specified for a composite model, *modelspec*<sub>1</sub> and *modelspec*<sub>2</sub> cannot have names in common; for example, `lrtest (A B C) (C D E)` is not allowed because both model specifications include C.

| <i>options</i>     | Description                                                        |
|--------------------|--------------------------------------------------------------------|
| <code>stats</code> | display statistical information about the two models               |
| <code>dir</code>   | display descriptive information about the two models               |
| <code>df(#)</code> | override the automatic degrees-of-freedom calculation; seldom used |
| <code>force</code> | force testing even when apparently invalid                         |

`collect` is allowed; see [U] [11.1.10 Prefix commands](#).

## Options

`stats` displays statistical information about the unrestricted and restricted models, including the information indices of Akaike and Schwarz.

`dir` displays descriptive information about the unrestricted and restricted models; see `estimates dir` in [R] [estimates store](#).

`df(#)` is seldom specified; it overrides the automatic degrees-of-freedom calculation.

`force` forces the likelihood-ratio test calculations to take place in situations where `lrtest` would normally refuse to do so and issue an error. Such situations arise when one or more assumptions of the test are violated, for example, if the models were fit with `vce(robust)`, `vce(cluster clustvar)`, or `pweights`; when the dependent variables in the two models differ; when the null log likelihoods differ; when the samples differ; or when the estimation commands differ. If you use the `force` option, there is no guarantee as to the validity or interpretability of the resulting test.

## Remarks and examples

The standard way to use `lrtest` is to do the following:

1. Fit either the restricted model or the unrestricted model by using one of Stata’s estimation commands and then store the results using `estimates store name`.
2. Fit the alternative model (the unrestricted or restricted model) and then type `‘lrtest name .’`. `lrtest` determines for itself which of the two models is the restricted model by comparing the degrees of freedom.

Often, you may want to store the alternative model with estimates store `name2`, for instance, if you plan additional tests against models yet to be fit. The likelihood-ratio test is then obtained as `lrtest name name2`.

Remarks are presented under the following headings:

*Nested models*  
*Composite models*

## Nested models

`lrtest` may be used with any estimation command that reports a log likelihood, including `heckman`, `logit`, `poisson`, `stcox`, and `streg`. You must check that one of the model specifications implies a statistical model that is *nested within* the model implied by the other specification. Usually, this means that both models are fit with the same estimation command (for example, both are fit by `logit`, with the same dependent variables) and that the set of covariates of one model is a subset of the covariates of the other model. Second, `lrtest` is valid only for models that are fit by maximum likelihood or by some equivalent method, so it does not apply to models that were fit with probability weights or clusters. Specifying the `vce(robust)` option similarly would indicate that you are worried about the valid specification of the model, so you would not use `lrtest`. Third, `lrtest` assumes that under the null hypothesis, the test statistic is (approximately) distributed as  $\chi^2$ . This assumption is not true for likelihood-ratio tests of “boundary conditions”, such as tests for the presence of overdispersion or random effects (Gutierrez, Carter, and Drukker 2001).

### ► Example 1

We have data on infants born with low birthweights along with the characteristics of the mother (Hosmer, Lemeshow, and Sturdivant 2013; see also [R] [logistic](#)). We fit the following model:

```
. use https://www.stata-press.com/data/r19/lbw
(Hosmer & Lemeshow data)
. logistic low age lwt i.race smoke ptl ht ui
Logistic regression Number of obs = 189
 LR chi2(8) = 33.22
 Prob > chi2 = 0.0001
Log likelihood = -100.724 Pseudo R2 = 0.1416
```

|       | Odds ratio | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|------------|-----------|-------|-------|----------------------|----------|
| low   |            |           |       |       |                      |          |
| age   | .9732636   | .0354759  | -0.74 | 0.457 | .9061578             | 1.045339 |
| lwt   | .9849634   | .0068217  | -2.19 | 0.029 | .9716834             | .9984249 |
| race  |            |           |       |       |                      |          |

Note: `_cons` estimates baseline odds.

We now wish to test the constraint that the coefficients on age, lwt, pt1, and ht are all zero or, equivalently here, that the odds ratios are all 1. One solution is to type

```
. test age lwt pt1 ht
(1) [low]age = 0
(2) [low]lwt = 0
(3) [low]pt1 = 0
(4) [low]ht = 0

 chi2(4) = 12.38
 Prob > chi2 = 0.0147
```

This test is based on the inverse of the information matrix and is therefore based on a quadratic approximation to the likelihood function; see [R] [test](#). A more precise test would be to refit the model, applying the proposed constraints, and then calculate the likelihood-ratio test.

We first save the current model:

```
. estimates store full
```

We then fit the constrained model, which here is the model omitting age, lwt, pt1, and ht:

```
. logistic low i.race smoke ui
Logistic regression Number of obs = 189
 LR chi2(4) = 18.80
 Prob > chi2 = 0.0009
Log likelihood = -107.93404 Pseudo R2 = 0.0801
```

| low   | Odds ratio | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|------------|-----------|-------|-------|----------------------|----------|
| race  |            |           |       |       |                      |          |
| Black | 3.052746   | 1.498087  | 2.27  | 0.023 | 1.166747             | 7.987382 |
| Other | 2.922593   | 1.189229  | 2.64  | 0.008 | 1.316457             | 6.488285 |
| smoke |            |           |       |       |                      |          |

|       | .1402209   | .0512295  | -5.38 | 0.000 | .0685216             | .2869447 |

Note: **\_cons** estimates baseline odds.

That done, `lrtest` compares this model with the model we previously stored:

```
. lrtest full .
Likelihood-ratio test
Assumption: . nested within full

 LR chi2(4) = 14.42
 Prob > chi2 = 0.0061
```

Let's compare results. `test` reported that age, lwt, pt1, and ht were jointly significant at the 1.5% level; `lrtest` reports that they are significant at the 0.6% level. Given the quadratic approximation made by `test`, we could argue that `lrtest`'s results are more accurate.

`lrtest` explicates the assumption that, from a comparison of the degrees of freedom, it has assessed that the last fit model (`.`) is nested within the model stored as `full`. In other words, `full` is the unconstrained model and `.` is the constrained model.

The names in “(Assumption: . nested in full)” are actually links. Click on a name, and the results for that model are replayed.

Aside: The `nestreg` command provides a simple syntax for performing likelihood-ratio tests for nested model specifications; see [R] [nestreg](#). In the [previous example](#), we fit a full logistic model, used `estimates store` to store the full model, fit a constrained logistic model, and used `lrtest` to report a likelihood-ratio test between two models. To do this with one call to `nestreg`, use the `lrtable` option.

#### □ Technical note

`lrtest` determines the degrees of freedom of a model as the rank of the (co)variance matrix  $e(V)$ . There are two issues here. First, the *numerical* determination of the rank of a matrix is a subtle problem that can, for instance, be affected by the scaling of the variables in the model. The rank of a matrix depends on the number of (independent) linear combinations of coefficients that sum exactly to zero. In the world of numerical mathematics, it is hard to tell whether a very small number is really nonzero or is a real zero that happens to be slightly off because of roundoff error from the finite precision with which computers make floating-point calculations. Whether a small number is being classified as one or the other, typically on the basis of a threshold, affects the determined degrees of freedom. Although Stata generally makes sensible choices, it is bound to make mistakes occasionally. The moral of this story is to make sure that the calculated degrees of freedom is as you expect before interpreting the results. □

#### □ Technical note

A second issue involves `regress` and related commands such as `anova`. Mainly for historical reasons, `regress` does not treat the residual variance,  $\sigma^2$ , the same way that it treats the regression coefficients. Type `estat vce` after `regress`, and you will see the regression coefficients, not  $\hat{\sigma}^2$ . Most estimation commands for models with ancillary parameters (for example, `streg` and `heckman`) treat all parameters as equals. There is nothing technically wrong with `regress` here; we are usually focused on the regression coefficients, and their estimators are uncorrelated with  $\hat{\sigma}^2$ . But, formally,  $\sigma^2$  adds a degree of freedom to the model, which does not matter if you are comparing two regression models by a likelihood-ratio test. This test depends on the difference in the degrees of freedom, and hence being “off by 1” in each does not matter. But, if you are comparing a regression model with a larger model—for example, a heteroskedastic regression model fit by `arch`—the automatic determination of the degrees of freedom is incorrect, and you must specify the `df (#)` option. □

### ▷ Example 2

Returning to the low-birthweight data in [example 1](#), we now wish to test that the coefficient on `2.race` (black) is equal to that on `3.race` (other). The base model is still stored under the name `full`, so we need only fit the constrained model and perform the test. With  $z$  as the index of the logit model, the base model is

$$z = \beta_0 + \beta_1 \text{age} + \beta_2 \text{lw} + \beta_3 2.\text{race} + \beta_4 3.\text{race} + \dots$$

If  $\beta_3 = \beta_4$ , this can be written as

$$z = \beta_0 + \beta_1 \text{age} + \beta_2 \text{lw} + \beta_3 (2.\text{race} + 3.\text{race}) + \dots$$

We can fit the constrained model as follows:

```
. constraint 1 2.race = 3.race
. logistic low age lwt i.race smoke ptl ht ui, constraints(1)
Logistic regression Number of obs = 189
 Wald chi2(7) = 25.17
Log likelihood = -100.9997 Prob > chi2 = 0.0007
(1) [low]2.race - [low]3.race = 0
```

|       | low | Odds ratio | Std. err. | z     | P> z  | [95% conf. interval] |          |
|-------|-----|------------|-----------|-------|-------|----------------------|----------|

| _cons |     | 1.309371   | 1.527398  | 0.23  | 0.817 | .1330839             | 12.8825  |

Note: **\_cons** estimates baseline odds.

Comparing this model with our original model, we obtain

```
. lrtest full .
Likelihood-ratio test
Assumption: . nested within full
LR chi2(1) = 0.55
Prob > chi2 = 0.4577
```

By comparison, typing `test 2.race=3.race` after fitting our base model results in a significance level of 0.4572. Alternatively, we can first store the restricted model, here using the name `equal`. Next, `lrtest` is invoked specifying the names of the restricted and unrestricted models (we do not care about the order). This time, we also add the option `stats` requesting a table of model statistics, including the model selection indices AIC and BIC.

```
. estimates store equal
. lrtest equal full, stats
Likelihood-ratio test
Assumption: equal nested within full
LR chi2(1) = 0.55
Prob > chi2 = 0.4577
Akaike's information criterion and Bayesian information criterion
```

| Model | N   | ll(null) | ll(model) | df | AIC      | BIC      |
|-------|-----|----------|-----------|----|----------|----------|
| equal | 189 | .        | -100.9997 | 8  | 217.9994 | 243.9334 |
| full  | 189 | -117.336 | -100.724  | 9  | 219.448  | 248.6237 |

Note: BIC uses N = number of observations. See [\[R\] IC note](#).

## Composite models

lrtest supports composite models; that is, models that can be fit by fitting a series of simpler models or by fitting models on subsets of the data. Theoretically, a composite model is one in which the likelihood function,  $L(\theta)$ , of the parameter vector,  $\theta$ , can be written as the product

$$L(\theta) = L_1(\theta_1) \times L_2(\theta_2) \times \cdots \times L_k(\theta_k)$$

of likelihood terms with  $\theta = (\theta_1, \dots, \theta_k)$  a partitioning of the full parameter vector. In such a case, the full-model likelihood  $L(\theta)$  is maximized by maximizing the likelihood terms  $L_j(\theta_j)$  in turn. Obviously,  $\log L(\hat{\theta}) = \sum_{j=1}^k \log L_j(\hat{\theta}_j)$ . The degrees of freedom for the composite model is obtained as the sum of the degrees of freedom of the constituting models.

### ▷ Example 3

As an example of the application of composite models, we consider a test of the hypothesis that the coefficients of a statistical model do not differ between different portions (“regimes”) of the covariate space. Economists call a test for such a hypothesis a *Chow test*.

We continue the analysis of the data on children of low birthweight by using logistic regression modeling and study whether the regression coefficients are the same among the three races: white, black, and other. A likelihood-ratio Chow test can be obtained by fitting the logistic regression model for each of the races and then comparing the combined results with those of the model previously stored as `full`. Because the full model included dummies for the three races, this version of the Chow test allows the intercept of the logistic regression model to vary between the regimes (races).

```
. logistic low age lwt smoke ptl ht ui if 1.race, nolog
Logistic regression Number of obs = 96
 LR chi2(6) = 13.86
 Prob > chi2 = 0.0312
Log likelihood = -45.927061 Pseudo R2 = 0.1311
```

Note: **\_cons** estimates baseline odds.

. estimates store other

We are now ready to perform the likelihood-ratio Chow test:

```
. lrtest (full) (white black other), stats
Likelihood-ratio test
Assumption: full nested within (white, black, other)
LR chi2(12) = 9.83
Prob > chi2 = 0.6310
Akaike's information criterion and Bayesian information criterion
```

| Model | N   | ll(null)  | ll(model) | df | AIC      | BIC      |
|-------|-----|-----------|-----------|----|----------|----------|
| full  | 189 | -117.336  | -100.724  | 9  | 219.448  | 248.6237 |
| white | 96  | -52.85752 | -45.92706 | 7  | 105.8541 | 123.8046 |
| black | 26  | -17.71291 | -12.65416 | 7  | 39.30831 | 48.11499 |
| other | 67  | -44.26039 | -37.22844 | 7  | 88.45689 | 103.8897 |

Note: BIC uses N = number of observations. See [\[R\] IC note](#).

We cannot reject the hypothesis that the logistic regression model applies to each of the races at any reasonable significance level. By specifying the `stats` option, we can verify the degrees of freedom of the test:  $12 = 7 + 7 + 7 - 9$ . We can obtain the same test by fitting an expanded model with interactions between all covariates and race.

```
. logistic low race##c.(age lwt smoke ptl ht ui)
Logistic regression
Log likelihood = -95.809661
Number of obs = 189
LR chi2(20) = 43.05
Prob > chi2 = 0.0020
Pseudo R2 = 0.1835
```

| Other        | 2.378976   | 2.476124  | 0.83  | 0.405 | .309335              | 18.29579 |
| _cons        | .4891008   | .993785   | -0.35 | 0.725 | .0091175             | 26.23746 |

Note: `_cons` estimates baseline odds.

```
. lrtest full .
Likelihood-ratio test
Assumption: full nested within .
LR chi2(12) = 9.83
Prob > chi2 = 0.6310
```

Applying `lrtest` for the full model against the model with all interactions yields the same test statistic and  $p$ -value as for the full model against the composite model for the three regimes. Here the specification of the model with interactions was convenient, and `logistic` had no problem computing the estimates for the expanded model. In models with more complicated likelihoods, such as Heckman's selection model (see [R] [heckman](#)) or complicated survival-time models (see [ST] [streg](#)), fitting the models with all interactions may be numerically demanding and may be much more time consuming than fitting a series of models separately for each regime.

Given the model with all interactions, we could also test the hypothesis of no differences among the regions (races) by a Wald version of the Chow test by using the `testparm` command; see [R] [test](#).

```
. testparm race#c.(age lwt smoke pt1 ht ui)
(1) [low]2.race#c.age = 0
(2) [low]3.race#c.age = 0
(3) [low]2.race#c.lwt = 0
(4) [low]3.race#c.lwt = 0
(5) [low]2.race#c.smoke = 0
(6) [low]3.race#c.smoke = 0
(7) [low]2.race#c.pt1 = 0
(8) [low]3.race#c.pt1 = 0
(9) [low]2.race#c.ht = 0
(10) [low]3.race#c.ht = 0
(11) [low]2.race#c.ui = 0
(12) [low]3.race#c.ui = 0

 chi2(12) = 8.24
 Prob > chi2 = 0.7663
```

We conclude that, here, the Wald version of the Chow test is similar to the likelihood-ratio version of the Chow test.

## Stored results

`lrtest` stores the following in `r()`:

Scalars

|                      |                                      |
|----------------------|--------------------------------------|
| <code>r(p)</code>    | $p$ -value for likelihood-ratio test |
| <code>r(df)</code>   | degrees of freedom                   |
| <code>r(chi2)</code> | LR test statistic                    |

Programmers wishing their estimation commands to be compatible with `lrtest` should note that `lrtest` requires that the following results be returned:

|                     |                                              |
|---------------------|----------------------------------------------|
| <code>e(cmd)</code> | name of estimation command                   |
| <code>e(ll)</code>  | log likelihood                               |
| <code>e(V)</code>   | variance-covariance matrix of the estimators |
| <code>e(N)</code>   | number of observations                       |

`lrtest` also verifies that `e(N)`, `e(ll_0)`, and `e(depvar)` are consistent between two noncomposite models.

## Methods and formulas

Let  $L_0$  and  $L_1$  be the log-likelihood values associated with the full and constrained models, respectively. The test statistic of the likelihood-ratio test is  $LR = -2(L_1 - L_0)$ . If the constrained model is true, LR is approximately  $\chi^2$  distributed with  $d_0 - d_1$  degrees of freedom, where  $d_0$  and  $d_1$  are the model degrees of freedom associated with the full and constrained models, respectively (Greene 2018, 554–555).

`lrtest` determines the degrees of freedom of a model as the rank of  $e(V)$ , computed as the number of nonzero diagonal elements of `invsym(e(V))`.

## Description

`lsens` graphs sensitivity and specificity versus probability cutoff and optionally creates new variables containing these data.

`lsens` requires that the current estimation results be from `logistic`, `logit`, `probit`, or `ivprobit`; see [\[R\] logistic](#), [\[R\] logit](#), [\[R\] probit](#), or [\[R\] ivprobit](#).

## Quick start

Graph sensitivity and specificity versus a probability cutoff using current estimation results

```
lsens
```

Generate variables `v1`, `v2`, and `v3` to contain probability cutoffs, sensitivity, and specificity

```
lsens, genprob(v1) gensens(v2) genspec(v3)
```

Add “My Title” to graph

```
lsens, genprob(v1) gensens(v2) genspec(v3) title(My Title)
```

## Menu

Statistics > Binary outcomes > Postestimation > Sensitivity/specificity plot

## Syntax

```
lsens [depvar] [if] [in] [weight] [, options]
```

## Options

### Main

`all` requests that the statistic be computed for all observations in the data, ignoring any `if` or `in` restrictions specified by the estimation command.

`genprob(varname)`, `gensens(varname)`, and `genspec(varname)` specify the names of new variables created to contain, respectively, the probability cutoffs and the corresponding sensitivity and specificity.

`replace` requests that existing variables specified for `genprob()`, `gensens()`, or `genspec()` be overwritten.

`nograph` suppresses graphical output.

### Advanced

`beta(matname)` specifies a row vector containing model coefficients. The columns of the row vector must be labeled with the corresponding names of the independent variables in the data. The dependent variable *depvar* must be specified immediately after the command name. See [Models other than the last fitted model](#) later in this entry.

## Plot

*connect\_options* affect the rendition of the plotted points connected by lines; see *connect\_options* in [G-2] [graph twoway scatter](#).

## Add plots

`addplot(plot)` provides a way to add other plots to the generated graph. See [G-3] [addplot\\_option](#).

## Y axis, X axis, Titles, Legend, Overall

*twoway\_options* are any of the options documented in [G-3] [twoway\\_options](#), excluding `by()`. These include options for titling the graph (see [G-3] [title\\_options](#)) and for saving the graph to disk (see [G-3] [saving\\_option](#)).

## Remarks and examples

Remarks are presented under the following headings:

[Introduction](#)

[Models other than the last fitted model](#)

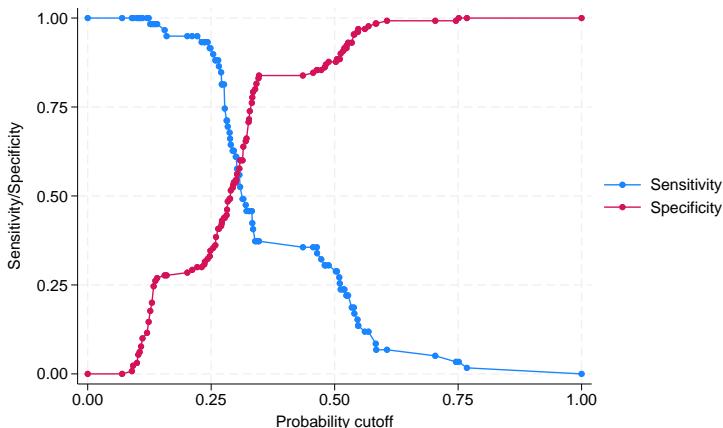

### Introduction

`lsens` plots sensitivity and specificity; it plots both sensitivity and specificity versus probability cutoff  $c$ . The graph is equivalent to what you would get from `estat classification` (see [R] [estat classification](#)) if you varied the cutoff probability  $c$  from 0 to 1.

#### ▷ Example 1

We illustrate `lsens` after `logistic`; see [R] [logistic](#).

```
. use https://www.stata-press.com/data/r19/lbw
(Hosmer & Lemeshow data)
. logistic low age i.race smoke ui
(output omitted)
. lsens
```

lsens optionally creates new variables containing the probability cutoff, sensitivity, and specificity.

```
. lsens, genprob(p) gensens(sens) genspec(spec) nograph
```

The variables created will have  $M + 2$  distinct nonmissing values: one for each of the  $M$  covariate patterns, one for  $c = 0$ , and another for  $c = 1$ . Values are recorded for  $p = 0$ , for each of the observed predicted probabilities, and for  $p = 1$ . The total number of observations required to do this can be fewer than  $\_N$ , the same as  $\_N$ , or  $\_N + 1$ , or  $\_N + 2$ . If more observations are added, they are added at the end of the dataset and the values of the original variables are set to missing in the added observations. How the values added align with existing observations is irrelevant.

## □ Technical note

logistic, logit, probit, or ivprobit and lsens keep track of the estimation sample. If you type, for instance, logistic ... if x==1, then when you type lsens, the statistics will be calculated on the x==1 subsample of the data automatically.

You should specify if or in with lsens only when you wish to produce graphs and calculate statistics for a set of observations other than the estimation sample.

If the logistic model was fit with fweights, lsens properly accounts for the weights in its calculations. You do not have to specify the weights when you run lsens. Weights should be specified with lsens only when you wish to use a different set of weights.

## Models other than the last fitted model

By default, lsens uses the last model fit. You may also directly specify the model to lsens by inputting a vector of coefficients with the beta() option and passing the name of the dependent variable *devar* to lsens.

## ▷ Example 2

Suppose that someone publishes the following logistic model of low birthweight:

$$\Pr(\text{low} = 1) = F(-0.02 \text{ age} - 0.01 \text{ lwt} + 1.3 \text{ black} + 1.1 \text{ smoke} + 0.5 \text{ pt1} + 1.8 \text{ ht} + 0.8 \text{ ui} + 0.5)$$

where  $F$  is the cumulative logistic distribution. These coefficients are not odds ratios; they are the equivalent of what logit produces.

We can see whether this model fits our data. First, we enter the coefficients as a row vector and label its columns with the names of the independent variables plus `_cons` for the constant (see [P] [matrix define](#) and [P] [matrix rownames](#)).

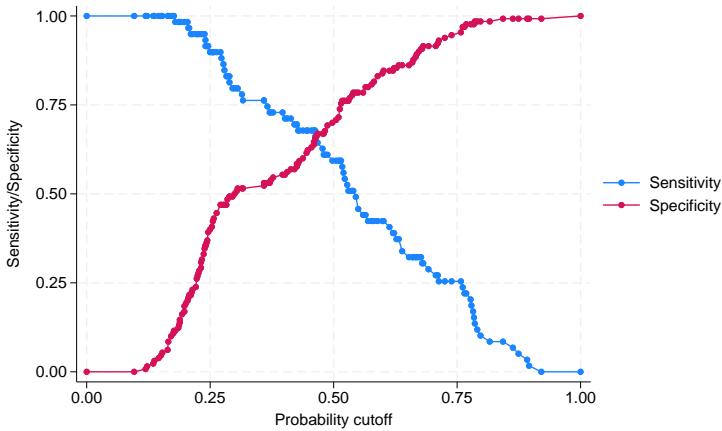

```
. use https://www.stata-press.com/data/r19/lbw3, clear
(Hosmer & Lemeshow data)
. matrix input b = (-0.02, -.01, 1.3, 1.1, .5, 1.8, .8, .5)
. matrix colnames b = age lwt black smoke pt1 ht ui _cons
```

We can use `lroc` (see [R] [lroc](#)) to examine the predictive ability of the model:

```
. lroc low, beta(b) nograph
Logistic model for low
Number of observations = 189
Area under ROC curve = 0.7275
```

The area under the curve indicates that this model does have some predictive power. We can obtain a graph of sensitivity and specificity as a function of the cutoff probability by typing

```
. lsens low, beta(b)
```

◀

## Stored results

`lsens` stores the following in `r()`:

```
Scalars
 r(N) number of observations
```

## Methods and formulas

Let  $j$  index observations and  $c$  be the cutoff probability. Let  $p_j$  be the predicted probability of a positive outcome and  $y_j$  be the actual outcome, which we will treat as 0 or 1, although Stata treats it as 0 and non-0, excluding missing observations.

A prediction is classified as *positive* if  $p_j \geq c$  and otherwise is classified as *negative*. The classification is *correct* if it is *positive* and  $y_j = 1$  or if it is *negative* and  $y_j = 0$ .

*Sensitivity* is the fraction of  $y_j = 1$  observations that are correctly classified. *Specificity* is the percentage of  $y_j = 0$  observations that are correctly classified.

## Description

`lv` shows a letter-value display (Tukey 1977, 44–49; Hoaglin 1983) for each variable in *varlist*. If no variables are specified, letter-value displays are shown for each numeric variable in the data.

## Quick start

Letter-value display for all numeric variables in the dataset

```
lv
```

Letter-value display for `v1`

```
lv v1
```

Also generate new variables `_mid`, `_spread`, `_psigma`, and `_z2` containing midsummaries, spreads, pseudosigmias, and  $z^2$  values

```
lv v1, generate
```

Letter-value displays for `v1` separately for each value of `v2`

```
bysort v2: lv v1
```

## Menu

Statistics > Summaries, tables, and tests > Distributional plots and tests > Letter-value display

## Syntax

```
lv [varlist] [if] [in] [, generate tail(#)]
```

`by` and `collect` are allowed; see [U] 11.1.10 Prefix commands.

## Options

### Main

`generate` adds four new variables to the data: `_mid`, containing the midsummaries; `_spread`, containing the spreads; `_psigma`, containing the pseudosigmias; and `_z2`, containing the squared values from a standard normal distribution corresponding to the particular letter value. If the variables `_mid`, `_spread`, `_psigma`, and `_z2` already exist, their contents are replaced. At most, only the first 11 observations of each variable are used; the remaining observations contain missing. If *varlist* specifies more than one variable, the newly created variables contain results for the last variable specified. The `generate` option may not be used with the `by` prefix.

`tail(#)` indicates the inverse of the tail density through which letter values are to be displayed: 2 corresponds to the median (meaning half in each tail), 4 to the fourths (roughly the 25th and 75th percentiles), 8 to the eighths, and so on. # may be specified as 4, 8, 16, 32, 64, 128, 256, 512, or 1,024 and defaults to a value of # that has corresponding depth just greater than 1. The default is taken as 1,024 if the calculation results in a number larger than 1,024. Given the intelligent default, this option is rarely specified.

## Remarks and examples

Letter-value displays are a collection of observations drawn systematically from the data, focusing especially on the tails rather than the middle of the distribution. The displays are called letter-value displays because letters have been (almost arbitrarily) assigned to tail densities:

| Letter | Tail area | Letter | Tail area |
|--------|-----------|--------|-----------|
| M      | 1/2       | B      | 1/64      |
| F      | 1/4       | A      | 1/128     |
| E      | 1/8       | Z      | 1/256     |
| D      | 1/16      | Y      | 1/512     |
| C      | 1/32      | X      | 1/1024    |

### ▷ Example 1

We have data on the mileage ratings of 74 automobiles. To obtain a letter-value display, we type

```
. use https://www.stata-press.com/data/r19/auto
(1978 automobile data)
. lv mpg
```

| #           | 74   | Mileage (mpg) |       |      | spread  | pseudosigma |
|-------------|------|---------------|-------|------|---------|-------------|
| M           | 37.5 |               | 20    |      |         |             |
| F           | 19   | 18            | 21.5  | 25   | 7       | 5.216359    |
| E           | 10   | 15            | 21.5  | 28   | 13      | 5.771728    |
| D           | 5.5  | 14            | 22.25 | 30.5 | 16.5    | 5.576303    |
| C           | 3    | 14            | 24.5  | 35   | 21      | 5.831039    |
| B           | 2    | 12            | 23.5  | 35   | 23      | 5.732448    |
| A           | 1.5  | 12            | 25    | 38   | 26      | 6.040635    |
|             | 1    | 12            | 26.5  | 41   | 29      | 6.16562     |
|             |      |               |       |      | # below | # above     |
| inner fence |      | 7.5           |       | 35.5 | 0       | 1           |
| outer fence |      | -3            |       | 46   | 0       | 0           |

The decimal points can be made to line up and thus the output made more readable by specifying a display format for the variable; see [U] 12.5 Formats: Controlling how data are displayed.

```
. format mpg %9.2f
. lv mpg
```

| #           | 74   | Mileage (mpg) |       |       |         |             |
|-------------|------|---------------|-------|-------|---------|-------------|
| M           | 37.5 |               | 20.00 |       | spread  | pseudosigma |
| F           | 19   | 18.00         | 21.50 | 25.00 | 7.00    | 5.22        |
| E           | 10   | 15.00         | 21.50 | 28.00 | 13.00   | 5.77        |
| D           | 5.5  | 14.00         | 22.25 | 30.50 | 16.50   | 5.58        |
| C           | 3    | 14.00         | 24.50 | 35.00 | 21.00   | 5.83        |
| B           | 2    | 12.00         | 23.50 | 35.00 | 23.00   | 5.73        |
| A           | 1.5  | 12.00         | 25.00 | 38.00 | 26.00   | 6.04        |
|             | 1    | 12.00         | 26.50 | 41.00 | 29.00   | 6.17        |
|             |      |               |       |       | # below | # above     |
| inner fence |      | 7.50          |       | 35.50 | 0       | 1           |
| outer fence |      | -3.00         |       | 46.00 | 0       | 0           |

At the top, the number of observations is indicated as 74. The first line shows the statistics associated with M, the letter value that puts half the density in each tail, or the median. The median has *depth* 37.5 (that is, in the ordered data, M is 37.5 observations in from the extremes) and has value 20. The next line shows the statistics associated with F or the fourths. The fourths have depth 19 (that is, in the ordered data, the lower fourth is observation 19, and the upper fourth is observation  $74 - 19 + 1$ ), and the values of the lower and upper fourths are 18 and 25. The number in the middle is the point halfway between the fourths—called a midsummary. If the distribution were perfectly symmetric, the midsummary would equal the median. The spread is the difference between the lower and upper summaries ( $25 - 18 = 7$ ). For fourths, half the data lie within a 7-mpg band. The pseudosigma is a calculation of the standard deviation using only the lower and upper summaries and assuming that the variable is normally distributed. If the data really were normally distributed, all the pseudosigmas would be roughly equal.

After the letter values, the line labeled with depth 1 reports the minimum and maximum values. Here the halfway point between the extremes is 26.5, which is greater than the median, indicating that 41 is more extreme than 12, at least relative to the median. And with each letter value, the midsummaries are increasing—our data are skewed. The pseudosigmas are also increasing, indicating that the data are spreading out relative to a normal distribution, although, given the evident skewness, this elongation may be an artifact of the skewness.

At the end is an attempt to identify outliers, although the points so identified are merely outside some predetermined cutoff. Points outside the inner fence are called *outside values* or *mild outliers*. Points outside the outer fence are called *severe outliers*. The inner fence is defined as  $(3/2)$ IQR and the outer fence as 3IQR above and below the F summaries, where the interquartile range (IQR) is the spread of the fourths.

◀

## □ Technical note

The form of the letter-value display has varied slightly with different authors. `lv` displays appear as described by Hoaglin (1983) but as modified by Emerson and Stoto (1983), where they included the midpoint of each of the spreads. This format was later adopted by Hoaglin (1985). If the distribution is symmetric, the midpoints will all be roughly equal. On the other hand, if the midpoints vary systematically, the distribution is skewed.

The pseudosigmas are obtained from the lower and upper summaries for each letter value. For each letter value, they are the standard deviation a normal distribution would have if its spread for the given letter value were to equal the observed spread. If the pseudosigmas are all roughly equal, the data are said to have *neutral elongation*. If the pseudosigmas increase systematically, the data are said to be more elongated than a normal, that is, have thicker tails. If the pseudosigmas decrease systematically, the data are said to be less elongated than a normal, that is, have thinner tails.

Interpretation of the number of mild and severe outliers is more problematic. The following discussion is drawn from [Hamilton \(1991\)](#):

Obviously, the presence of any such outliers does not rule out that the data have been drawn from a normal distribution; in large datasets, there will most certainly be observations outside  $(3/2)IQR$  and  $3IQR$ . Severe outliers, however, make up about two per million (0.0002%) of a normal population. In samples, they lie far enough out to have substantial effects on means, standard deviations, and other classical statistics. The 0.0002%, however, should be interpreted carefully; outliers appear more often in small samples than one might expect from population proportions because of sampling variation in estimated quartiles. Monte Carlo simulation by [Hoaglin, Iglewicz, and Tukey \(1986\)](#) obtained these results on the percentages and numbers of outliers in random samples from a normal population:

| $n$      | Percentage   |        | Number       |          |
|----------|--------------|--------|--------------|----------|
|          | any outliers | severe | any outliers | severe   |
| 10       | 2.83         | 0.362  | 0.283        | 0.0362   |
| 20       | 1.66         | 0.074  | 0.332        | 0.0148   |
| 50       | 1.15         | 0.011  | 0.575        | 0.0055   |
| 100      | 0.95         | 0.002  | 0.95         | 0.002    |
| 200      | 0.79         | 0.001  | 1.58         | 0.002    |
| 300      | 0.75         | 0.001  | 2.25         | 0.003    |
| $\infty$ | 0.70         | 0.0002 | $\infty$     | $\infty$ |

Thus, the presence of any severe outliers in samples of less than 300 is sufficient to reject normality. [Hoaglin, Iglewicz, and Tukey \(1981\)](#) suggested the approximation  $0.00698 + 0.4/n$  for the fraction of mild outliers in a sample of size  $n$  or, equivalently,  $0.00698n + 0.4$  for the number of outliers.

□

## ► Example 2

The `generate` option adds the `_mid`, `_spread`, `_psigma`, and `_z2` variables to our data, making possible many of the diagnostic graphs suggested by [Hoaglin \(1985\)](#).

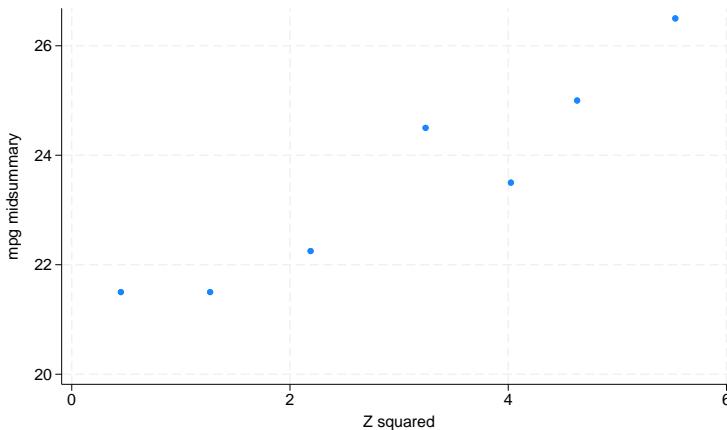

```
. lv mpg, generate
 (output omitted)
. list _mid _spread _psigma _z2 in 1/12
```

|     | _mid  | _spread | _psigma  | _z2      |
|-----|-------|---------|----------|----------|
| 1.  | 20    | .       | .        | .        |
| 2.  | 21.5  | 7       | 5.216359 | .4501955 |
| 3.  | 21.5  | 13      | 5.771728 | 1.26828  |
| 4.  | 22.25 | 16.5    | 5.576303 | 2.188846 |
| 5.  | 24.5  | 21      | 5.831039 | 3.24255  |
| 6.  | 23.5  | 23      | 5.732448 | 4.024532 |
| 7.  | 25    | 26      | 6.040635 | 4.631499 |
| 8.  | .     | .       | .        | .        |
| 9.  | .     | .       | .        | .        |
| 10. | .     | .       | .        | .        |
| 11. | 26.5  | 29      | 6.16562  | 5.53073  |
| 12. | .     | .       | .        | .        |

Observations 12 through the end are missing for these new variables. The definition of the observations is always the same. The first observation contains the M summary; the second, the F; the third, the E; and so on. Observation 11 always contains the summary for depth 1. Observations 8–10—corresponding to letter values Z, Y, and X—contain missing because these statistics were not calculated. We have only 74 observations, and their depth would be 1.

[Hoaglin \(1985\)](#) suggests graphing the midsummary against  $z^2$ . If the distribution is not skewed, the points in the resulting graph will be along a horizontal line:

```
. scatter _mid _z2
```

The graph clearly indicates the skewness of the distribution. We might also graph `_psigma` against `_z2` to examine elongation.

◀

## Stored results

`lv` stores the following in `r()`:

Scalars

|                        |                        |                     |              |
|------------------------|------------------------|---------------------|--------------|
| <code>r(N)</code>      | number of observations | <code>r(u_C)</code> | upper 32nd   |
| <code>r(min)</code>    | minimum                | <code>r(l_B)</code> | lower 64th   |
| <code>r(max)</code>    | maximum                | <code>r(u_B)</code> | upper 64th   |
| <code>r(median)</code> | median                 | <code>r(l_A)</code> | lower 128th  |
| <code>r(l_F)</code>    | lower 4th              | <code>r(u_A)</code> | upper 128th  |
| <code>r(u_F)</code>    | upper 4th              | <code>r(l_Z)</code> | lower 256th  |
| <code>r(l_E)</code>    | lower 8th              | <code>r(u_Z)</code> | upper 256th  |
| <code>r(u_E)</code>    | upper 8th              | <code>r(l_Y)</code> | lower 512th  |
| <code>r(l_D)</code>    | lower 16th             | <code>r(u_Y)</code> | upper 512th  |
| <code>r(u_D)</code>    | upper 16th             | <code>r(l_X)</code> | lower 1024th |
| <code>r(l_C)</code>    | lower 32nd             | <code>r(u_X)</code> | upper 1024th |

The lower/upper 8ths, 16ths, ..., 1024ths will be defined only if there are sufficient data.

## Methods and formulas

Let  $N$  be the number of (nonmissing) observations on  $x$ , and let  $x_{(i)}$  refer to the ordered data when  $i$  is an integer. Define  $x_{(i+0.5)} = (x_{(i)} + x_{(i+1)})/2$ ; the median is defined as  $x_{\{(N+1)/2\}}$ .

Define  $x_{[d]}$  as the pair of numbers  $x_{(d)}$  and  $x_{(N+1-d)}$ , where  $d$  is called the *depth*. Thus,  $x_{[1]}$  refers to the minimum and maximum of the data. Define  $m = (N + 1)/2$  as the depth of the median,  $f = (\lfloor m \rfloor + 1)/2$  as the depth of the fourths,  $e = (\lfloor f \rfloor + 1)/2$  as the depth of the eighths, and so on. Depths are reported on the far left of the letter-value display. The corresponding fourths of the data are  $x_{[f]}$ , the eighths are  $x_{[e]}$ , and so on. These values are reported inside the display. The middle value is defined as the corresponding midpoint of  $x_{[1]}$ . The spreads are defined as the difference in  $x_{[1]}$ .

The corresponding point  $z_i$  on a standard normal distribution is obtained as (Hoaglin 1985, 456–457)

$$z_i = \begin{cases} F^{-1}\{(d_i - 1/3)/(N + 1/3)\} & \text{if } d_i > 1 \\ F^{-1}\{0.695/(N + 0.390)\} & \text{otherwise} \end{cases}$$

where  $d_i$  is the depth of the letter value. The corresponding pseudosigma is obtained as the ratio of the spread to  $-2z_i$  (Hoaglin 1985, 431).

Define  $(F_l, F_u) = x_{[f]}$ . The inner fence has cutoffs  $F_l - \frac{3}{2}(F_u - F_l)$  and  $F_u + \frac{3}{2}(F_u - F_l)$ . The outer fence has cutoffs  $F_l - 3(F_u - F_l)$  and  $F_u + 3(F_u - F_l)$ .

The inner-fence values reported by `lv` are almost equal to those used by `graph`, `box` to identify outside points. The only difference is that `graph` uses a slightly different definition of fourths, namely, the 25th and 75th percentiles as defined by `summarize`; see [R] [summarize](#).

## Description

`makespline` generates a set of variables that form B-spline, piecewise polynomial spline, and restricted cubic spline basis functions from a list of existing variables. B-spline and piecewise polynomial spline bases may be first, second, or third order, with knots at percentiles of the data or uniformly spaced over the range of the variables. Restricted cubic splines, also known as natural splines, may only be of third order.

## Quick start

Generate variables from `x1` and `x2` that form third-order B-spline basis functions, with one knot at the median of each variable

```
makespline bspline x1 x2
```

Same as above, but with three knots at the 25th, 50th, and 75th percentiles

```
makespline bspline x1 x2, knots(3)
```

Same as above, but use second-order B-splines

```
makespline bspline x1 x2, knots(3) order(2)
```

Generate variables that form a linear spline for `x1` with knots at 10 and 20

```
makespline piecewise x1, knotslist(10 20) order(1)
```

Same as above, but do not rescale `x1` before creating spline variables

```
makespline piecewise x1, knotslist(10 20) order(1) norescalevars
```

Generate variables that form third-order piecewise polynomial splines for `x1` and `x2`, with knots at their 25th, 50th, and 75th percentiles

```
makespline piecewise x1 x2, knots(3)
```

Same as above, but with three knots at evenly spaced points over the range of `x1` and of `x2`

```
makespline piecewise x1 x2, knots(3) uniformknots
```

Specify values of knots in matrix `K` to generate variables forming restricted cubic splines

```
makespline rcs x1 x2, knotsmat(K)
```

Generate variables that form a linear spline for `x1` without rescaling the values of `x1`

```
makespline linear x1
```

| <b>Main</b>                             |                                                                                                                                   |
| <code>bsepsilon(#)</code>               | specify the distance (#) from the variable's boundary for B-spline knot placement; default is <code>bsepsilon(0.01)</code>        |
| <code>local</code>                      | generate first-order polynomial spline variables centered around adjacent knots                                                   |
| <code>harrell</code>                    | place knots according to percentiles in <a href="#">Harrell (2001)</a> ; only for <code>rbs</code> basis                          |
| <code>order(#)</code>                   | use a spline basis of order #; default is <code>order(3)</code>                                                                   |
| <code>knots(#)</code>                   | use a spline basis function with # knots                                                                                          |
| <code>knotslist(knotvals)</code>        | use knots specified in <i>knotvals</i>                                                                                            |
| <code>knotsmat(matname)</code>          | use knots in matrix <i>matname</i>                                                                                                |
| <code>distinct(#)</code>                | set minimum number of distinct values required for variables used to construct splines to #; default is <code>distinct(10)</code> |
| <code>replace</code>                    | replace existing variables having the same names as the new basis and rescaled variables, if they exist                           |
| <code>norescalevars</code>              | do not rescale variables before generating spline basis                                                                           |
| <code>uniformknots</code>               | place knots at evenly spaced points over the range of each variable; default is placement at percentiles                          |
| <code>float</code>                      | set type for generated variables to float instead of double                                                                       |
| <code>basis(stub   newvarlist)</code>   | store elements of spline basis function using <i>stub</i> or <i>newvarlist</i>                                                    |
| <code>rescale(stub   newvarlist)</code> | store rescaled values of variables using <i>stub</i> or <i>newvarlist</i>                                                         |

`collect` is allowed; see [U] [11.1.10 Prefix commands](#).

`fweights`, `awweights`, and `iweights` are allowed; see [U] [11.1.6 weight](#).

## Options

### Main

`bsepsilon(#)` specifies the distance from the boundary of the variable where B-spline knots may be placed. The default is `bsepsilon(0.01)`.

`local` specifies that a basis function for a first-order piecewise polynomial be generated with variables centered around adjacent knots. When splines are generated for only one variable and used in estimation, the regression coefficients measure slopes for the intervals defined by knots.

`harrell` specifies that knots be placed according to the percentiles recommended in [Harrell \(2001, 23\)](#). This option may be used only with *basis* `rbs` and when specifying 3 to 7 knots.

`order(#)` specifies that a spline of order `#` be used as the basis. `order()` may be 1, 2, or 3 for *basis bspline* and *basis piecewise*. `order()` may only be 3 for *basis rcs*. For *basis linear* or when the `local` option is specified, `order()` may only be 1. The default is `order(3)`, cubic splines.

`knots(#)` specifies that a spline or B-spline basis function with `#` interior knots be used. The number of knots must be an integer greater than or equal to 1. The maximum number of knots is either 4,096 or two-thirds of the sample size, whichever is smaller. Also, the number of knots must be less than the number of distinct values in the variable used to generate the basis function. The default is `knots(1)` if exact knot values are not specified using `knotslist()` or `knotsmat()`. For *basis rcs*, the default is `knots(3)`, and the number of knots must be 3 or greater.

`knotslist(knotvals)` specifies in *knotvals* the values of knots to be used for each variable. The knot values must be specified in the order of *varlist*, and a backslash (`\`) must be used to separate knots for different variables. For example, if splines are generated for `x1` and `x2`, the knots may be specified as `knotslist(20 40 60 \ 5 10 15)`.

`knotsmat(matname)` specifies that, in *matname*, the knots for each variable be the values in each row. The number of knots should be the same for each variable, and there must be as many rows as there are variables. If rows of *matname* are not labeled with *varnames*, then rows are assumed to be in the order of *varlist*.

`distinct(#)` specifies the minimum number of distinct values required for the variables used to construct the basis functions. Intuitively, using discrete variables for continuous interpolation is difficult to justify. `#` specifies the number of distinct values necessary for a variable to be considered continuous. The default is `distinct(10)`.

`replace` specifies that the variables generated to form the basis function be replaced. If `basis(stub | newvarlist)` or `rescale(stub | newvarlist)` are specified, the variables named with *stub*, or those listed in *newvarlist*, are replaced. Otherwise, variables with the default names are replaced.

`norescalevars` specifies that the original values of the variables in *varlist* be used to generate the basis function. By default, variables are first rescaled to  $[0, 1]$ . `norescalevars` may not be used with *basis bspline* or *basis linear*.

`uniformknots` specifies that knots be placed at evenly spaced points over the range of each variable. The default is placement at percentiles of each of the specified variables.

`float` specifies that variables be generated as floats. Because of numerical precision and stability, the default is `double`.

`basis(stub | newvarlist)` specifies that the elements of the basis function be generated with the specified names.

When *stub* is specified, this prefix is used to generate enumerated variables for each element of the basis function.

When *newvarlist* is specified, variables with these names are generated for the elements of the basis function.

`rescale(stub | newvarlist)` specifies that the rescaled variables used to generate the basis function be stored with the specified names. This option applies only to *basis piecewise* and *basis rcs*.

When *stub* is specified, this prefix is used to generate enumerated variables for the rescaled variables.

When *newvarlist* is specified, variables with these names are generated for the rescaled variables.

## Remarks and examples

`makespline` generates new variables that form B-splines, piecewise polynomial splines, and restricted cubic splines from existing variables. Splines allow for different low-order polynomials in different regions of the original variables, and they approximate a smooth function by continuously connecting these low-order polynomials. Knots define the boundaries of the regions.

The standard piecewise polynomial variables created by `makespline` `piecewise` allow the functions to be linear, quadratic, or cubic in each region. `makespline` `linear` provides a convenient method for creating linear splines from the original variables, without rescaling. This is useful when you wish to directly interpret regression coefficients in the metric of the original variables. The terms in the standard piecewise polynomial spline function can be highly collinear and may be numerically unstable when used in estimation. B-splines, which can be created by `makespline` `bspline`, avoid this problem by creating orthogonal spline terms. For an introduction to piecewise polynomial splines and B-splines, see *Piecewise polynomial splines and B-splines* in [R] [npregress intro](#). `makespline` `rccs` creates restricted cubic splines, also known as natural splines, in which the function is linear before the first knot, cubic between adjacent knots, and linear again after the last knot. This can improve performance in the tails over the standard cubic spline.

In addition to selecting the type of spline, `makespline` allows you to specify the location of knots—the locations where the function changes. You can specify the number of knots you wish to allow, and `makespline` will place the knots based on percentiles of the data or uniformly spaced across the range of values in the data. Alternatively, you can specify the exact values at which you wish the knots to be placed.

Regardless of the type of spline, we can refer to our newly created variables as a spline basis function. A basis is a collection of terms that can approximate a smooth function arbitrarily well. A basis function, such as one of the spline functions created by `makespline`, is a subset of the basis terms that can be used to approximate the mean function.

The basis function variables generated by `makespline` are useful for nonparametric and semiparametric estimation. For instance, `makespline` can be used when we want to fit models such as

$$\mathbf{y} = \mathbf{x}_1\beta + g(\mathbf{x}_2, \mathbf{x}_3, \dots, \mathbf{x}_k) + \epsilon \quad (1)$$

In the expression above, the outcome  $\mathbf{y}$ , the covariates  $\mathbf{x}_1, \dots, \mathbf{x}_k$ , and the unobservable  $\epsilon$  are  $n \times 1$  vectors of covariates. The function  $g(\cdot)$  is unknown and  $\mathbf{x}_1$  enters the model linearly. These types of models are commonly used when we are interested in estimating the effect of  $\mathbf{x}_1$  on the mean of  $\mathbf{y}$ . We are agnostic about the functional form in which the controls,  $\mathbf{x}_2, \dots, \mathbf{x}_k$ , enter the model, but to get a precise estimate of the effect of  $\mathbf{x}_1$ , we need a reliable approximation of  $g(\cdot)$ . We may use `makespline` to generate the basis functions that best approximate  $g(\cdot)$  and then use the basis functions to fit the model in (1).

For instance, we can generate basis functions with `basis` as the stub name:

```
makespline bspline x2-x5, basis(basis)
```

This would generate a third-order B-spline basis function for each of the variables in `x2-x5`, with knots at the medians of `x2-x5`. Each of the basis functions would consist of five variables; see *Methods and formulas* in [R] [npregress series](#) for details.

The default naming convention is to give the elements of the basis function a name that starts with `_bsp` and two subscripts. The first subscript enumerates the basis functions, and the second subscript enumerates the elements within the basis function. For example, if we created basis functions for two variables, we would obtain the following:

```
. makespline bspline price mpg, replace
. describe _*
```

| Variable name         | Storage type | Display format | Value label | Variable label                  |
|-----------------------|--------------|----------------|-------------|---------------------------------|
| <code>_bsp_1_1</code> | double       | %10.0g         |             | B-spline basis term 1 for price |
| <code>_bsp_1_2</code> | double       | %10.0g         |             | B-spline basis term 2 for price |
| <code>_bsp_1_3</code> | double       | %10.0g         |             | B-spline basis term 3 for price |
| <code>_bsp_1_4</code> | double       | %10.0g         |             | B-spline basis term 4 for price |
| <code>_bsp_1_5</code> | double       | %10.0g         |             | B-spline basis term 5 for price |
| <code>_bsp_2_1</code> | double       | %10.0g         |             | B-spline basis term 1 for mpg   |
| <code>_bsp_2_2</code> | double       | %10.0g         |             | B-spline basis term 2 for mpg   |
| <code>_bsp_2_3</code> | double       | %10.0g         |             | B-spline basis term 3 for mpg   |
| <code>_bsp_2_4</code> | double       | %10.0g         |             | B-spline basis term 4 for mpg   |
| <code>_bsp_2_5</code> | double       | %10.0g         |             | B-spline basis term 5 for mpg   |

If we want to change the stub name `_bsp` to `autobasis`, we could use the `basis()` option as follows:

```
. makespline bspline price mpg, basis(autobasis)
. describe auto*
```

| Variable name              | Storage type | Display format | Value label | Variable label                  |
|----------------------------|--------------|----------------|-------------|---------------------------------|
| <code>autobasis_1_1</code> | double       | %10.0g         |             | B-spline basis term 1 for price |
| <code>autobasis_1_2</code> | double       | %10.0g         |             | B-spline basis term 2 for price |
| <code>autobasis_1_3</code> | double       | %10.0g         |             | B-spline basis term 3 for price |
| <code>autobasis_1_4</code> | double       | %10.0g         |             | B-spline basis term 4 for price |
| <code>autobasis_1_5</code> | double       | %10.0g         |             | B-spline basis term 5 for price |
| <code>autobasis_2_1</code> | double       | %10.0g         |             | B-spline basis term 1 for mpg   |
| <code>autobasis_2_2</code> | double       | %10.0g         |             | B-spline basis term 2 for mpg   |
| <code>autobasis_2_3</code> | double       | %10.0g         |             | B-spline basis term 3 for mpg   |
| <code>autobasis_2_4</code> | double       | %10.0g         |             | B-spline basis term 4 for mpg   |
| <code>autobasis_2_5</code> | double       | %10.0g         |             | B-spline basis term 5 for mpg   |

Alternatively, we could provide names for each of the variables that form a basis function. For example,

```
. makespline bspline mpg, basis(mpg1 mpg2 mpg3 mpg4 mpg5)
. describe mpg1-mpg5
```

| Variable name     | Storage type | Display format | Value label | Variable label                |
|-------------------|--------------|----------------|-------------|-------------------------------|
| <code>mpg1</code> | double       | %10.0g         |             | B-spline basis term 1 for mpg |
| <code>mpg2</code> | double       | %10.0g         |             | B-spline basis term 2 for mpg |
| <code>mpg3</code> | double       | %10.0g         |             | B-spline basis term 3 for mpg |
| <code>mpg4</code> | double       | %10.0g         |             | B-spline basis term 4 for mpg |
| <code>mpg5</code> | double       | %10.0g         |             | B-spline basis term 5 for mpg |

## ► Example 2: Generating and naming piecewise polynomial spline basis functions

Below, we generate a third-order piecewise polynomial spline with one knot at the median and show the variables we generated:

```
. makespline piecewise mpg
. describe *_sp*
```

| Variable name | Storage type | Display format | Value label | Variable label                            |
|---------------|--------------|----------------|-------------|-------------------------------------------|
| _rs_sp_1      | double       | %10.0g         |             | mpg rescaled to [0,1]                     |
| _sp_1_1       | double       | %10.0g         |             | Piecewise polynomial basis term 1 for mpg |

The only syntactical difference is that, after `makespline`, we specify `piecewise` instead of `bspline` to be the basis. `makespline` generates two variables in this case. They are the elements that are necessary to construct a basis function.

The default naming convention is to give the elements of the spline function a name that starts with `_sp` and has two subscripts. The first subscript enumerates the piecewise polynomial spline for a given variable, and the second subscript denotes the knot number. The rescaled variable starts with `_rs_sp` followed by a subscript denoting the element in the variable list.

Again, we may use a stub to modify the names that precede the subscripts, or we may specify a name for each new variable. Below, we also specified the names for the rescaled variables:

```
. makespline piecewise mpg price, basis(mpgsp pricesp) rescale(mpgrs pricers)
. describe mpgsp mpgrs pricesp pricers
```

| Variable name | Storage type | Display format | Value label | Variable label                              |
|---------------|--------------|----------------|-------------|---------------------------------------------|
| mpgsp         | double       | %10.0g         |             | Piecewise polynomial basis term 1 for mpg   |
| mpgrs         | double       | %10.0g         |             | mpg rescaled to [0,1]                       |
| pricesp       | double       | %10.0g         |             | Piecewise polynomial basis term 1 for price |
| pricers       | double       | %10.0g         |             | price rescaled to [0,1]                     |

The logic behind the variables generated is that they consist of all the elements needed to approximate the unknown function  $g(\cdot)$  of the specified variables nonparametrically. In this case, a third-order piecewise polynomial spline approximation of  $g(\cdot)$  consists of the levels, square, and cube of `mpgsp`, `mpgrs`, `pricesp`, and `pricers`. Specifically, to include the fully interacted basis functions in a model, we would need to include the term below in our specification:

```
c.(c.mpgrs##c.mpgrs##c.mpgrs mpgsp)##c.(c.pricers##c.pricers##c.pricers pricesp)
```

`makespline` simplifies this task by returning a local macro with the terms needed to fit  $g(\cdot)$ . The local macro has the name `r(regressors)`. In this case, it expands to the following:

```
. display "r(regressors)'"
c.(c.mpgrs##c.mpgrs##c.mpgrs mpgsp)##c.(c.pricers##c.pricers##c.pricers pricesp)
```

Note that when you generate basis functions for more than one variable, as we did above, `r(regressors)` fully interacts these basis functions. These fully interacted basis functions can be included when fitting a model by adding `'r(regressors)'` to your list of covariates.

### ▷ Example 3: Using makespline in semiparametric estimation

As we mentioned previously, basis functions are particularly useful for approximating unknown functions. For example, say we want to obtain the average marginal effect of  $x_1$  on the conditional mean of the continuous outcome  $y$ . We have two controls,  $x_2$  and  $x_3$ , but it is unclear whether they enter the model linearly or with another functional form.

To approximate the unknown function of  $x_2$  and  $x_3$ , we construct two B-spline basis functions with eight knots each. We use the simulated dataset and then the `makespline bspline` command:

```
. use https://www.stata-press.com/data/r19/splines, clear
(Simulated data)
. makespline bspline x2 x3, knots(8)
```

This yields basis functions with 12 elements. Once you fully interact the two basis functions, you get 168 regressors. Using all of them to approximate the unknown function would not be a sound idea. Thus, we will use `poregress` to perform partialing-out lasso linear regression. This estimator will select from the 168 covariates to provide a good approximation to the unknown function and at the same time provide a reliable estimate of the marginal effect of interest.

Rather than interact the basis terms manually, we can simply refer to the macro `r(regressors)`, which contains the full interaction of the basis functions:

```
. poregress y x1, controls('r(regressors)')
Estimating lasso for y using plugin
Estimating lasso for x1 using plugin
Partialing-out linear model
```

|  |                             |   |         |
|--|-----------------------------|---|---------|
|  | Number of obs               | = | 5,000   |
|  | Number of controls          | = | 168     |
|  | Number of selected controls | = | 19      |
|  | Wald chi2(1)                | = | 3535.78 |
|  | Prob > chi2                 | = | 0.0000  |

| y  | Robust      |           | z     | P> z  | [95% conf. interval] |          |
|----|-------------|-----------|-------|-------|----------------------|----------|
|    | Coefficient | std. err. |       |       |                      |          |
| x1 | 2.951242    | .049632   | 59.46 | 0.000 | 2.853965             | 3.048519 |

Note: Chi-squared test is a Wald test of the coefficients of the variables of interest jointly equal to zero. Lassos select controls for model estimation. Type `lassoinfo` to see number of selected variables in each lasso.

We obtain an average marginal effect of 2.95.

A researcher does not know the true value of the effect; however, we do. These are simulated data. The model is given by

$$\mathbf{y} = 3\mathbf{x}_1 + 3\sin\{3(\mathbf{x}_2 - \mathbf{x}_3)\} + \epsilon$$

The unknown function of  $\mathbf{x}_2$  and  $\mathbf{x}_3$  is complex, yet we obtained a precise estimate of the average marginal effect.

### ► Example 4: Using makespline for estimation and graphing

It is common to use linear splines to create a graph after estimation. The knots of a regressor define a piecewise polynomial that can be visualized conditional on the values of other covariates.

Below, we study the effect of mileage in miles per gallon (mpg) on car prices (price). We regress price on mpg, three linear polynomial basis terms defined by knots at the quartiles of mpg, and a dummy variable, foreign (1 if cars are foreign).

We first generate the variables that form the polynomial basis and then fit the regression.

```
. sysuse auto, clear
(1978 automobile data)
. makespline linear mpg, knots(3) basis(mpg)
. regress price mpg mpg_* i.foreign
```

| Source   | SS        | df | MS         | Number of obs | = | 74     |
|----------|-----------|----|------------|---------------|---|--------|
|          |           |    |            | F(5, 68)      | = | 13.49  |
| Model    | 316201619 | 5  | 63240323.8 | Prob > F      | = | 0.0000 |
| Residual | 318863777 | 68 | 4689173.19 | R-squared     | = | 0.4979 |

| foreign |             |           |       |       |                      |
| Foreign | 1676.381    | 609.4723  | 2.75  | 0.008 | 460.1983 2892.564    |
| _cons   | 28796.47    | 3449.408  | 8.35  | 0.000 | 21913.28 35679.65    |

The regression line for our model is given by the following command:

```
generate double xb = _b[_cons] + _b[1.foreign]*foreign + ///
mpg*_b[mpg] + (mpg>18)*(mpg-18)*_b[mpg_1_1] + ///
(mpg>20)*(mpg-20)*_b[mpg_1_2] + ///
(mpg>25)*(mpg-25)*_b[mpg_1_3]
```

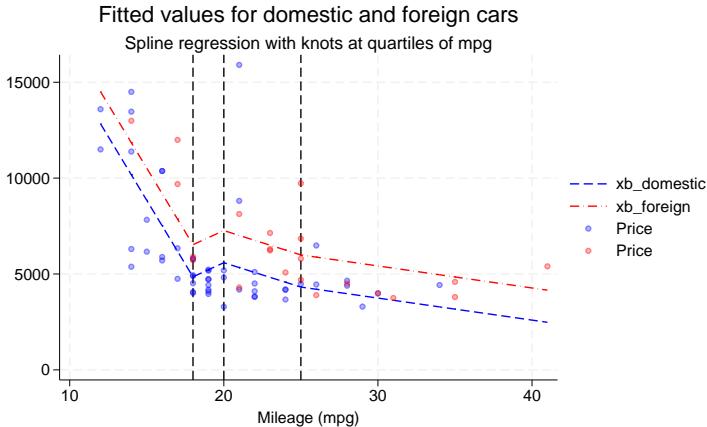

The effect of mpg changes at the knots. If mpg is less than or equal to 18, it is  $\_b[mpg]$ ; if it is greater than 18 but less than or equal to 20, it is  $(\_b[mpg] + \_b[mpg\_1\_1])$ ; if it is greater than 20 but less than or equal to 25, it is  $(\_b[mpg] + \_b[mpg\_1\_1] + \_b[mpg\_1\_2])$ ; and if it is greater than 25, it is  $(\_b[mpg] + \_b[mpg\_1\_1] + \_b[mpg\_1\_2] + \_b[mpg\_1\_3])$ .

We can plot regression lines for foreign and domestic cars. We first generate the predictions for foreign and domestic cars.

```
. generate xb_domestic = _b[_cons] + mpg*_b[mpg]
> + (mpg>18)*(mpg-18)*_b[mpg_1_1]
> + (mpg>20)*(mpg-20)*_b[mpg_1_2]
> + (mpg>25)*(mpg-25)*_b[mpg_1_3]
. generate xb_foreign = _b[_cons] + _b[1.foreign] + mpg*_b[mpg]
> + (mpg>18)*(mpg-18)*_b[mpg_1_1]
> + (mpg>20)*(mpg-20)*_b[mpg_1_2]
> + (mpg>25)*(mpg-25)*_b[mpg_1_3]
```

Then we plot both regression lines referencing the placement of the knots with vertical lines. In the graph, we also include the values of the dependent variable. We can inspect graphically how the effect of mpg differs across the regions defined by the knots.

```
. twoway line xb_domestic mpg,
> lcolor(blue) lpattern(dash) sort ||
> line xb_foreign mpg,
> lcolor(red) lpatter(dash_dot) sort ||
> scatter price mpg if foreign==0, mcolor(blue%30) ||
> scatter price mpg if foreign==1, mcolor(red%30)
> xline(18 20 25)
> title(Fitted values for domestic and foreign cars)
> subtitle(Spline regression with knots at quartiles of mpg)
```

## Methods and formulas

See *Methods and formulas* in [R] [npregress series](#) for piecewise polynomial spline and B-spline computation.

When the `local` option is specified, let  $V_i$ ,  $i = 1, \dots, n$ , be the variables to be created;  $k_i$ ,  $i = 1, \dots, n - 1$ , be the corresponding knots; and  $\mathcal{V}$  be the original variable rescaled to be in  $[0, 1]$ . Then

$$\begin{aligned} V_1 &= \min(\mathcal{V}, k_1) \\ V_i &= \max\left\{\min(\mathcal{V}, k_i), k_{i-1}\right\} - k_{i-1} \quad i = 2, \dots, n - 1 \\ V_n &= \max(\mathcal{V}, k_{n-1}) - k_{n-1} \end{aligned}$$

When the `rcs` basis is specified, let  $k_i$ ,  $i = 1, \dots, n$ , be the knot values;  $V_i$ ,  $i = 1, \dots, n - 1$ , be the variables to be created; and  $\mathcal{V}$  be the original variable rescaled to be in  $[0, 1]$ . Then

$$\begin{aligned} V_1 &= \mathcal{V} \\ V_{i+1} &= \frac{(\mathcal{V} - k_i)_+^3 - (k_n - k_{n-1})^{-1}\{(\mathcal{V} - k_{n-1})_+^3(k_n - k_i) - (\mathcal{V} - k_n)_+^3(k_{n-1} - k_i)\}}{(k_n - k_1)^2} \\ & \quad i = 1, \dots, n - 2 \end{aligned}$$

where

$$(u)_+ = \begin{cases} u, & \text{if } u > 0 \\ 0, & \text{if } u \leq 0 \end{cases}$$

When the `harrell` option is specified, the knots are placed using the percentiles recommended in [Harrell \(2001, 23\)](#). These percentiles are based on the chosen number of knots as follows:

| No.<br>of knots | Percentiles |       |       |      |       |       |      |
|-----------------|-------------|-------|-------|------|-------|-------|------|
|                 | 10          | 50    | 90    |      |       |       |      |
| 3               | 10          | 50    | 90    |      |       |       |      |
| 4               | 5           | 35    | 65    | 95   |       |       |      |
| 5               | 5           | 27.5  | 50    | 72.5 | 95    |       |      |
| 6               | 5           | 23    | 41    | 59   | 77    | 95    |      |
| 7               | 2.5         | 18.33 | 34.17 | 50   | 65.83 | 81.67 | 97.5 |

## Description

Margins are statistics calculated from predictions of a previously fit model at fixed values of some covariates and averaging or otherwise integrating over the remaining covariates.

The `margins` command estimates margins of responses for specified values of covariates and presents the results as a table.

Capabilities include estimated marginal means (also called least-squares means); adjusted predictions and adjusted treatment means; predictive margins (also called potential-outcome means); average and conditional adjusted predictions; and average and conditional marginal and partial effects, which may be reported as derivatives or as elasticities.

## Quick start

*Estimated marginal means (least-squares means)*

Estimated marginal mean of  $y$  for each level of  $a$  after `anova y a##b`  
`margins a, asbalanced`

Estimated marginal mean of  $y$  for each level of the interaction of  $a$  and  $b$  after `anova y a##b##c`  
`margins a#b, asbalanced`

Estimated marginal means of  $y_1$ ,  $y_2$ , and  $y_3$  for each level of  $a$  after `manova y1 y2 y3 = a##b`  
`margins a, asbalanced`

*Adjusted means and adjusted predictions*

Adjusted mean of  $y$  for each level of  $a$  when  $x$  is at its mean after `regress y i.a x`  
`margins a, atmeans`

Same as above, but set  $x$  to 10 rather than to its mean  
`margins a, at(x=10)`

Same as above, and also report adjusted means for  $x = 20$ ,  $x = 30$ , and  $x = 40$   
`margins a, at(x=(10(10)40))`

Adjusted predicted probability of  $y = 1$  for each level of  $a$  when  $x$  is at its mean after `logit y a##c.x`  
`margins a, atmeans`

Adjusted predicted probability for each level of the interaction of  $a$  and  $b$ , holding  $x$  at 25, after `logit y a##b##c.x`  
`margins a#b, at(x=25)`

Adjusted prediction for each level of  $a$  when  $x = 25$  and  $b = 1$   
`margins a, at(x=25 b=1)`

*Predictive margins and potential-outcome means*

Overall predictive margin, the average predicted probability of  $y = 1$ , after `logit y a##b x1 x2`  
`margins`

Predictive margins (potential-outcome means) for each level of `a`  
`margins a`

Predictive margins for `a`, when `x1` is set to 10, 20, 30, and 40  
`margins a, at(x1=(10(10)40))`

Predictive margins for levels of the interaction of `a` and `b`  
`margins a#b`

Predictive margins for `a` for all combinations of `x1 = 10, 20, 30` and `x2 = 50, 100, 150`  
`margins a, at(x1=(10(10)30) x2=(50(50)150))`

Predictive margins for `a`, first for `x1 = 10, 20, 30` with `x2` at its observed values, then for `x2 = 50, 100, 150` with `x1` at its observed values  
`margins a, at(x1=(10(10)30)) at(x2=(50(50)150))`

Predictive margins for `a` after `svy:logit y a##b x1 x2`  
`margins a, vce(unconditional)`

Average predicted probabilities of  $y = 1, y = 2, \dots$  after `mlogit y x1 x2 i.a`  
`margins`

Predictive margins for each level of `a` for each outcome of `y`  
`margins a`

*Average marginal effects and average partial effects*

Average marginal effect of `x1` on the predicted probability of  $y = 1$  after `probit y c.x1##c.x2##a` with continuous `x1` and `x2` and binary `a`  
`margins, dydx(x1)`

Average marginal effect (average partial effect) of binary `a`  
`margins, dydx(a)`

Average marginal effect of `x1` when `x2` is set to 10, 20, 30, and 40  
`margins, dydx(x1) at(x2=(10(10)40))`

Average marginal effect of `x1` when `a` is set to 0 and then to 1  
`margins a, dydx(x1)`

Average marginal effect of each variable in the model  
`margins, dydx(*)`

Average marginal effect of all variables on the truncated expected value of  $y, e(0, .)$ , after `tobit y x1 x2 x3, ll(0)`  
`margins, dydx(*) predict(e(0, .))`

Same as above, and report marginal effects for censored expected value of  $y$ ,  $y_{\text{star}}(0, .)$ , and for the linear prediction,  $xb$

```
margins, dydx(*) predict(e(0,.)) predict(ystar(0,.)) predict(xb)
```

### *Conditional marginal effects and conditional partial effects*

Marginal effect of  $x_1$  on the predicted probability of  $y = 1$ , setting all variables to their means, after `probit y c.x1#c.x2##a` with continuous  $x_1$  and  $x_2$  and binary  $a$

```
margins, dydx(x1) atmeans
```

Marginal effect (partial effect) of  $a$  when all variables are set to their means

```
margins, dydx(a) atmeans
```

Marginal effect of  $x_1$  when  $a = 0$  and  $x_1$  and  $x_2$  are set to their means

```
margins, dydx(x1) at(a=0 (mean) x1 x2)
```

Same as above

```
margins, dydx(x1) at(a=0) atmeans
```

Marginal effect of  $x_1$  when for all possible combinations of  $a = 0, 1$ ,  $x_1 = 50, 100$ , and  $x_2 = 10, 20, 30, 40$

```
margins a, dydx(x1) at(x1=(50 100) x2=(10(10)40))
```

Marginal effects of  $x_1$ ,  $x_2$ , and  $a$  with all variables set to their means

```
margins, dydx(*) atmeans
```

## Menu

Statistics > Postestimation

## Syntax

```
margins [marginlist] [if] [in] [weight] [, response_options options]
```

where *marginlist* is a list of factor variables or interactions that appear in the current estimation results. The variables may be typed with or without the *i.* prefix, and you may use any factor-variable syntax:

```
. margins i.sex i.group i.sex#i.group
. margins sex group sex#i.group
. margins sex##group
```

| <i>response_options</i>              | Description                                             |

| <code>within(<i>varlist</i>)</code>     | estimate margins at unique values of the nesting factors in <i>varlist</i>                                         |
| <b>Contrast</b>                         |                                                                                                                    |
| <code>contrast_options</code>           | any options documented in [R] <a href="#">margins, contrast</a>                                                    |
| <b>Pairwise comparisons</b>             |                                                                                                                    |
| <code>pwcompare_options</code>          | any options documented in [R] <a href="#">margins, pwcompare</a>                                                   |
| <b>SE</b>                               |                                                                                                                    |
| <code>vce(delta)</code>                 | estimate SEs using delta method; the default                                                                       |
| <code>vce(unconditional)</code>         | estimate SEs allowing for sampling of covariates                                                                   |
| <code>nose</code>                       | do not estimate SEs                                                                                                |
| <b>Advanced</b>                         |                                                                                                                    |
| <code>noweights</code>                  | ignore weights specified in estimation                                                                             |
| <code>noesample</code>                  | do not restrict margins to the estimation sample                                                                   |
| <code>emptycells(<i>empspec</i>)</code> | treatment of empty cells for balanced factors                                                                      |
| <code>estimtolerance(<i>tol</i>)</code> | specify numerical tolerance used to determine estimable functions;<br>default is <code>estimtolerance(1e-5)</code> |
| <code>noestimcheck</code>               | suppress estimability checks                                                                                       |
| <code>force</code>                      | estimate margins despite potential problems                                                                        |
| <code>chainrule</code>                  | use the chain rule when computing derivatives                                                                      |
| <code>nochainrule</code>                | do not use the chain rule                                                                                          |
| <b>Reporting</b>                        |                                                                                                                    |
| <code>level(#)</code>                   | set confidence level; default is <code>level(95)</code>                                                            |
| <code>mcompare(<i>method</i>)</code>    | adjust for multiple comparisons; default is <code>mcompare(noadjust)</code>                                        |
| <code>noatlegend</code>                 | suppress legend of fixed covariate values                                                                          |
| <code>post</code>                       | post margins and their VCE as estimation results                                                                   |
| <code>display_options</code>            | control columns and column formats, row spacing, line width and<br>factor-variable labeling                        |
| <code>df(#)</code>                      | use <i>t</i> distribution with # degrees of freedom for computing <i>p</i> -values<br>and confidence intervals     |

---

| <i>method</i>                       | Description                                         |
|-------------------------------------|-----------------------------------------------------|
| <code>noadjust</code>               | do not adjust for multiple comparisons; the default |
| <code>bonferroni [adjustall]</code> | Bonferroni's method; adjust across all terms        |
| <code>sidak [adjustall]</code>      | Šidák's method; adjust across all terms             |
| <code>scheffe</code>                | Scheffé's method                                    |

Time-series operators are allowed if they were used in the estimation.

See `at()` under *Options* for a description of *atspec*.

`collect` is allowed; see [U] 11.1.10 **Prefix commands**.

`fweights`, `awweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 **weight**.

`df(#)` does not appear in the dialog box.

## Options

*Warning: The option descriptions are brief and use jargon. Skip to [Remarks and examples](#) if you are reading about margins for the first time.*

Main

`predict(pred_opt)` and `expression(pnl_exp)` are mutually exclusive; they specify the response. If neither is specified, the response will be the default prediction that would be produced by `predict` after the underlying estimation command. Some estimation commands, such as `mlogit`, document a different default prediction for margins than for `predict`.

`predict(pred_opt)` specifies the option(s) to be specified with the `predict` command to produce the variable that will be used as the response. After estimation by `logistic`, you could specify `predict(xb)` to obtain linear predictions rather than the `predict` command's default, the probabilities.

Multiple `predict()` options can be specified to compute margins of multiple predictions simultaneously.

`expression(pnl_exp)` specifies the response as an expression. See [R] [predictnl](#) for a full description of `pnl_exp`. After estimation by `logistic`, you might specify `expression(exp(predict(xb)))` to use relative odds rather than probabilities as the response. For examples, see [Example 12: Margins of a specified expression](#).

`dydx(varlist)`, `eyex(varlist)`, `dyex(varlist)`, and `eydx(varlist)` request that margins report derivatives of the response with respect to `varlist` rather than on the response itself. `eyex()`, `dyex()`, and `eydx()` report derivatives as elasticities; see [Expressing derivatives as elasticities](#).

`continuous` is relevant only when one of `dydx()` or `eydx()` is also specified. It specifies that the levels of factor variables be treated as continuous; see [Derivatives versus discrete differences](#). This option is implied if there is a single-level factor variable specified in `dydx()` or `eydx()`.

`grand` specifies that the overall margin be reported. `grand` is assumed when `marginlist` is empty.

At

`at(atspec)` specifies values for covariates to be treated as fixed. By default, margins are calculated using observed values of covariates.

`at(age=20)` fixes covariate `age` to the value specified. `at()` may be used to fix continuous or factor covariates.

`at(age=20 sex=1)` simultaneously fixes covariates `age` and `sex` at the values specified.

`at(age=(20 30 40 50))` fixes `age` first at 20, then at 30, .... `margins` produces separate results for each specified value.

`at(age=(20(10)50))` does the same as `at(age=(20 30 40 50))`; that is, you may specify a numlist.

`at((mean) age (median) distance)` fixes the covariates at the summary statistics specified.

`at((p25) _all)` fixes all covariates at their 25th percentile values. See [Syntax of at\(\)](#) for the full list of summary-statistic modifiers.

`at((mean) _all (median) x x2=1.2 z=(1 2 3))` is processed from general to specific, with settings for named covariates overriding general settings specified via `_all`. Thus, all covariates are fixed at their means except for `x` (fixed at its median), `x2` (fixed at 1.2), and `z` (fixed first at 1, then at 2, and finally at 3).

`at((means) _all (asobserved) x2)` is a convenient way to set all covariates except `x2` to the mean.

Multiple `at()` options can be specified, and each will produce a different set of margins.

See [Syntax of at\(\)](#) for more information.

`atmeans` specifies that covariates be fixed at their means and is shorthand for `at((mean) _all)`. `atmeans` differs from `at((mean) _all)` in that `atmeans` will affect subsequent `at()` options. For instance,

```
. margins ..., atmeans at((p25) x) at((p75) x)
```

produces two sets of margins with both sets evaluated at the means of all covariates except `x`.

`asbalanced` is shorthand for `at((asbalanced) _factor)` and specifies that factor covariates be evaluated as though there were an equal number of observations in each level; see [Obtaining margins as though the data were balanced](#). `asbalanced` differs from `at((asbalanced) _factor)` in that `asbalanced` will affect subsequent `at()` options in the same way as `atmeans` does.

When `asbalanced` is combined with the `atmeans` option, factor variables are treated as balanced, while continuous covariates are fixed at their means. The resulting margin is known as an [adjusted treatment mean](#).

if/in/over

`over(varlist)` specifies that separate sets of margins be estimated for the groups defined by `varlist`. The variables in `varlist` must contain nonnegative integer (or missing) values. The variables need not be covariates in your model. When `over()` is combined with the `vce(unconditional)` option, each group is treated as a subpopulation; see [\[SVY\] Subpopulation estimation](#).

`subpop([varname] [if])` is intended for use with the `vce(unconditional)` option. It specifies that margins be estimated for the single subpopulation identified by the indicator variable or by the `if` expression or by both. Zero or missing indicates that the observation be excluded; nonzero or non-

missing, that it be included. See [SVY] [Subpopulation estimation](#) for why `subpop()` is preferred to `if` expressions and `in` ranges when also using `vce(unconditional)`. If `subpop()` is used without `vce(unconditional)`, it is treated merely as an additional `if` qualifier.

#### Within

`within(varlist)` allows for nested designs. `varlist` contains the nesting variable(s) over which margins are to be estimated. See [Obtaining margins with nested designs](#). As with `over(varlist)`, when `within(varlist)` is combined with `vce(unconditional)`, each level of the variables in `varlist` is treated as a subpopulation.

#### Contrast

`contrast_options` are any of the options documented in [R] [margins, contrast](#).

#### Pairwise comparisons

`pwcompare_options` are any of the options documented in [R] [margins, pwcompare](#).

#### SE

`vce(delta)` and `vce(unconditional)` specify how the VCE and, correspondingly, standard errors are calculated.

`vce(delta)` is the default. The delta method is applied to the formula for the response and the VCE of the estimation command. This method assumes that values of the covariates used to calculate the response are given or, if all covariates are not fixed using `at()`, that the data are given.
